

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

### Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

### About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

## PREFACE

---

OF course anybody may read the famous *Memoirs* of Amagat in the original; but everybody cannot so easily get these papers permanently into his possession. I believe, therefore, with the present translations to have scored a point in the interest of accessibility, and thus to have materially contributed to the advancement of science.

# A DEFENCE OF THE DOCTRINE TOUCHING THE SPRING AND WEIGHT OF THE AIR\*

By ROBERT BOYLE

---

## PART II., CHAPTER V.

TWO NEW EXPERIMENTS TOUCHING THE MEASURE OF THE FORCE OF THE  
SPRING OF AIR COMPRESSED AND DILATED

. . . . .

We took then a long glass-tube, which, by a dexterous hand and the help of a lamp, was in such a manner crooked at the bottom, that the part turned up was almost parallel to the rest of the tube, and the orifice of this shorter leg of the siphon (if I may so call the whole instrument) being hermetically sealed, the length of it was divided into inches (each of which was subdivided into eight parts) by a streight list of paper, which containing those divisions, was carefully pasted all along it. Then putting in as much quicksilver as served to fill the arch or bended part of the siphon, that the mercury standing in a level might reach in the one leg to the bottom of the divided paper, and just to the same height or horizontal line in the other; we took care, by frequently inclining the tube, so that the air might freely pass from one leg into the other by the sides of the mercury (we took, I say, care) that the air at last included in the shorter cylinder should be of the same laxity with the rest of the air about it. This done, we began to pour quicksilver into the longer leg of the siphon, which by its weight pressing up that in the shorter leg, did by degrees streighten

\* Selected from Boyle's *New Physico-Mechanical Experiments*, London, 1662.

## MEMOIRS ON

the included air : and continuing this pouring in of quicksilver till the air in the shorter leg was by condensation reduced to take up but half the space it possessed (I say, possessed, not filled) before ; we cast our eyes upon the longer leg of the glass, on which was likewise pasted a list of paper carefully divided into inches and parts, and we observed, not without delight and satisfaction, that the quicksilver in that longer part of the tube was 29 inches higher than the other. Now that this observation does both very well agree with and confirm our hypothesis, will be easily discerned by him that takes notice what we teach ; and Monsieur Paschal and our English friend's experiments prove, that the greater the weight is that leans upon the air, the more forcible is its endeavour of dilatation, and consequently its power of resistance (as other springs are stronger when bent by greater weights). For this being considered, it will appear to agree rarely-well with the hypothesis, that as according to it the air in that degree of density and correspondent measure of resistance, to which the weight of the incumbent atmosphere had brought it, was able to counter-balance and resist the pressure of a mercurial cylinder of about 29 inches, as we are taught by the Torricellian experiment ; so here the same air being brought to a degree of density about twice as great as that it had before, obtains a spring twice as strong as formerly. As may appear by its being able to sustain or resist a cylinder of 29 inches in the longer tube, together with the weight of the atmospherical cylinder, that leaned upon those 29 inches of mercury ; and, as we just now inferred from the Torricellian experiment, was equivalent to them.

We were hindered from prosecuting the trial at that time by the casual breaking of the tube. But because an accurate experiment of this nature would be of great importance to the doctrine of the spring of the air, and has not yet been made (that I know) by any man ; and because also it is more uneasy to be made than one would think, in regard of the difficulty as well of procuring crooked tubes fit for the purpose, as of making a just estimate of the true place of the protuberant mercury's surface ; I suppose it will not be unwelcome to the reader to be informed, that after some other trials, one of which we made in a tube whose longer leg was perpendicular, and the other, that contained the air, parallel to the horizon, we at last procured a tube of the figure expressed in the scheme ; which

# THE LAWS OF GASES

tube, though of a pretty bigness, was so long, that the cylinder, whereof the shorter leg of it consisted, admitted a list of paper, which had before been divided into 12 inches and their quarters, and the longer leg admitted another list of paper of divers feet in length, and divided after the same manner. Then quicksilver being poured in to fill up the bended part of the glass, that the surface of it in either leg might rest in the same horizontal line, as we lately taught, there was more and more quicksilver poured into the longer tube; and notice being watchfully taken how far the mercury was risen in that longer tube, when it appeared to have ascended to any of the divisions in the shorter tube, the several observations that were thus successively made, and as they were made set down, afforded us the ensuing table :

A TABLE OF THE CONDENSATION OF THE AIR

A	A	B	C	D	E	
48	12	00	Added to 22 $\frac{1}{8}$ makes	29 $\frac{2}{16}$	29 $\frac{2}{16}$	A. The number of equal spaces in the shorter leg, that contained the same parcel of air diversely extended.
46	11 $\frac{1}{2}$	01 $\frac{7}{16}$		30 $\frac{2}{16}$	33 $\frac{6}{16}$	
44	11	02 $\frac{13}{16}$		31 $\frac{6}{16}$	31 $\frac{12}{16}$	
42	10 $\frac{1}{2}$	04 $\frac{6}{16}$		33 $\frac{8}{16}$	33 $\frac{1}{4}$	
40	10	06 $\frac{3}{16}$		35 $\frac{6}{16}$	35	
38	9 $\frac{1}{2}$	07 $\frac{14}{16}$		37	36 $\frac{1}{2}$	B. The height of the mercurial cylinder in the longer leg, that compressed the air into those dimensions.
36	9	10 $\frac{2}{16}$		39 $\frac{5}{16}$	38 $\frac{7}{8}$	
34	8 $\frac{1}{2}$	12 $\frac{8}{16}$		41 $\frac{10}{16}$	41 $\frac{2}{17}$	
32	8	15 $\frac{1}{16}$		44 $\frac{3}{16}$	43 $\frac{11}{16}$	
30	7 $\frac{1}{2}$	17 $\frac{10}{16}$		47 $\frac{1}{16}$	46 $\frac{3}{8}$	
28	7	21 $\frac{3}{16}$		50 $\frac{6}{16}$	50	C. The height of the mercurial cylinder, that counterbalanced the pressure of the atmosphere.
26	6 $\frac{1}{2}$	25 $\frac{3}{16}$		54 $\frac{1}{16}$	53 $\frac{1}{3}$	
24	6	29 $\frac{11}{16}$		58 $\frac{13}{16}$	58 $\frac{3}{8}$	
23	5 $\frac{3}{4}$	32 $\frac{3}{16}$		61 $\frac{5}{16}$	60 $\frac{1}{2}$	
22	5 $\frac{1}{2}$	34 $\frac{15}{16}$		64 $\frac{1}{16}$	63 $\frac{6}{11}$	
21	5 $\frac{1}{4}$	37 $\frac{1}{2}$		67 $\frac{1}{16}$	66 $\frac{1}{4}$	D. The aggregate of the two last columns, B and C, exhibiting the pressure sustained by the included air.
20	5	41 $\frac{9}{16}$		70 $\frac{11}{16}$	70	
19	4 $\frac{3}{4}$	45		74 $\frac{2}{16}$	73 $\frac{11}{16}$	
18	4 $\frac{1}{2}$	48 $\frac{13}{16}$		77 $\frac{11}{16}$	77 $\frac{3}{8}$	
17	4 $\frac{1}{4}$	53 $\frac{11}{16}$		82 $\frac{13}{16}$	82 $\frac{4}{17}$	
16	4	58 $\frac{2}{16}$		87 $\frac{14}{16}$	87 $\frac{3}{8}$	E. What that pressure should be according to the hypothesis, that supposes the pressures and expansions to be in reciprocal proportion.
15	3 $\frac{3}{4}$	63 $\frac{15}{16}$		93 $\frac{1}{16}$	93 $\frac{1}{8}$	
14	3 $\frac{1}{2}$	71 $\frac{5}{16}$		100 $\frac{7}{16}$	99 $\frac{1}{4}$	
13	3 $\frac{1}{4}$	78 $\frac{11}{16}$		107 $\frac{13}{16}$	107 $\frac{1}{13}$	
12	3	88 $\frac{1}{16}$		117 $\frac{9}{16}$	116 $\frac{1}{8}$	
				5		

## MEMOIRS ON

For the better understanding of this experiment, it may not be amiss to take notice of the following particulars :

1. That the tube being so tall that we could not conveniently make use of it in a chamber, we were fain to use it on a pair of stairs, which were yet very lightsome, the tube being for preservation's sake by strings so suspended that it did scarce touch the box presently to be mentioned.

2. The lower and crooked part of the pipe was placed in a square wooden box, of a good largeness and depth, to prevent the loss of the quicksilver, that might fall aside in the transfusion from the vessel into the pipe, and to receive the whole quicksilver in case the tube should break.

3. That we were two to make the observation together, the one to take notice at the bottom, how the quicksilver rose in the shorter cylinder, and the other to pour in at the top of the longer ; it being very hard and troublesome for one man alone to do both accurately.

4. That the quicksilver was poured in but by little and little, according to the direction of him that observed below ; it being far easier to pour in more than to take out any, in case too much at once had been poured in.

5. That at the beginning of the operation, that we might the more truly discern where the quicksilver rested from time to time, we made use of a small looking-glass held in a convenient posture to reflect to the eye what we desired to discern.

6. That when the air was so compressed as to be crowded into less than a quarter of the space it possessed before, we tried whether the cold of a linen cloth dipped in water would then condense it. And it sometimes seemed a little to shrink, but not so manifestly that we dare build anything upon it. We then tried likewise, whether heat would, notwithstanding so forcible a compressure, dilate it ; and approaching the flame of a candle to that part where the air was pent up, the heat had a more sensible operation than the cold had before ; so that we scarce doubted, but that the expansion of the air would, notwithstanding the weight that compressed it, have been made conspicuous, if the fear of unseasonably breaking the glass had not kept us from increasing the heat.

Now although we deny not, but that in our table some particulars do not so exactly answer to what our formerly mentioned hypothesis might perchance invite the reader to expect ;

## THE LAWS OF GASES

yet the variations are not so considerable, but that they may probably enough be ascribed to some such want of exactness as in such nice experiments is scarce avoidable. But for all that, till further trial hath more clearly informed me, I shall not venture to determine whether or no the intimated theory will hold universally and precisely, either in condensation of air or rarefaction : all that I shall now urge being, that however the trial already made sufficiently proves the main thing, for which I here allege it ; since by it, it is evident, that as common air, when reduced to half its wonted extent, obtained near about twice as forcible a spring as it had before ; so this thus compressed air being further thrust into half this narrow room, obtained thereby a spring about as strong again as that it last had, and consequently four times as strong as that of the common air. And there is no cause to doubt, that if we had been here furnished with a greater quantity of quicksilver and a very strong tube, we might, by a further compression of the included air, have made it counterbalance the pressure of a far taller and heavier cylinder of mercury. For no man perhaps yet knows how near to an infinite compression the air may be capable of, if the compressing force be competently increased.

And to let you see, that we did not (as a little above) inconsiderately mention the weight of the incumbent atmospherical cylinder as a part of the weight resisted by the imprisoned air, we will here annex, that we took care, when the mercurial cylinder in the longer leg of the pipe was about an hundred inches high, to cause one to suck at the open orifice ; whereupon (as we expected) the mercury in the tube did notably ascend. . . . And therefore we shall render this reason of it that the pressure of the incumbent air being in part taken off by its expanding itself into the sucker's dilated chest, the imprisoned air was thereby enabled to dilate itself manifestly, and repel the mercury, that compressed it, till there was an equality of force betwixt the strong spring of that compressed air on the one part, and the tall mercurial cylinder, together with the contiguous dilated air, on the other part.

Now, if to what we have thus delivered concerning the compression of the air, we add some observations concerning its spontaneous expansion, it will the better appear, how much the phenomena of these mercurial experiments depend upon

# MEMOIRS ON

the differing measures of strength to be met with in the air's spring, according to its various degrees of compression and laxity.

A TABLE OF THE RAREFACTION OF THE AIR

	A	B	C	D	E
A. The number of equal spaces at the top of the tube, that contained the same parcel of air.	1	00 $\frac{3}{8}$		29 $\frac{3}{4}$	29 $\frac{3}{4}$
	1 $\frac{1}{2}$	10 $\frac{3}{8}$		19 $\frac{1}{8}$	19 $\frac{1}{8}$
	2	15 $\frac{3}{8}$		14 $\frac{3}{8}$	14 $\frac{1}{8}$
	3	20 $\frac{3}{8}$		9 $\frac{3}{8}$	9 $\frac{1}{2}$
B. The height of the mercurial cylinder, that together with the spring of the included air counterbalanced the pressure of the atmosphere.	4	22 $\frac{3}{8}$	Subtracted from 29 $\frac{3}{4}$ leaves	7 $\frac{1}{8}$	7 $\frac{1}{8}$
	5	24 $\frac{1}{8}$		5 $\frac{5}{8}$	5 $\frac{1}{2}$
	6	24 $\frac{7}{8}$		4 $\frac{7}{8}$	4 $\frac{3}{4}$
	7	25 $\frac{1}{8}$		4 $\frac{3}{8}$	4 $\frac{1}{4}$
	8	26 $\frac{3}{8}$		3 $\frac{3}{8}$	3 $\frac{3}{4}$
	9	26 $\frac{3}{8}$		3 $\frac{3}{8}$	3 $\frac{1}{8}$
C. The pressure of the atmosphere.	10	26 $\frac{3}{8}$		3 $\frac{3}{8}$	2 $\frac{3}{8}$
	12	27 $\frac{1}{8}$		2 $\frac{5}{8}$	2 $\frac{3}{8}$
	14	27 $\frac{1}{8}$		2 $\frac{3}{8}$	2 $\frac{1}{8}$
D. The complement of B to C, exhibiting the pressure sustained by the included air.	16	27 $\frac{1}{8}$		2 $\frac{3}{8}$	1 $\frac{5}{8}$
	18	27 $\frac{1}{8}$		1 $\frac{1}{8}$	1 $\frac{1}{2}$
	20	28 $\frac{3}{8}$		1 $\frac{3}{8}$	1 $\frac{3}{8}$
	24	28 $\frac{3}{8}$		1 $\frac{1}{8}$	1 $\frac{3}{8}$
E. What that pressure should be, according to the hypothesis.	28	28 $\frac{3}{8}$		1 $\frac{3}{8}$	1 $\frac{1}{8}$
	32	28 $\frac{1}{8}$		1 $\frac{3}{8}$	0 $\frac{1}{8}$

To make the experiment of the debilitated force of expanded air the plainer, it will not be amiss to note some particulars, especially touching the manner of making the trial; which (for the reasons lately mentioned) we have made on a light-some pair of stairs, and with a box also lined with paper to receive the mercury that might be spilt. And in regard it would require a vast and in few places procurable quantity of quicksilver, to imploy vessels of such kind as are ordinary in the Torricellian experiment, we made use of a glass-tube of about six feet long; for that being hermetically sealed at one end, served our turn as well as if we could have made the experiment in a tub or pond of seventy inches deep.

Secondly, We also provided a slender glass-pipe of about the

## THE LAWS OF GASES

bigness of a swan's quill, and open at both ends ; all along which was pasted a narrow list of paper, divided into inches and half quarters.

Thirdly, This slender pipe being thrust down into the greater tube almost filled with quicksilver, the glass helped to make it swell to the top of the tube ; and the quicksilver getting in at the lower orifice of the pipe, filled it up until the mercury included in that was near about a level with the surface of the surrounding mercury in the tube.

Fourthly, There being, as near as we could guess, little more than an inch of the slender pipe left above the surface of the restagnant mercury, and consequently unfilled therewith, the prominent orifice was carefully closed with sealing wax melted ; after which the pipe was let alone for a while, that the air, dilated a little by the heat of the wax, might, upon refrigeration, be reduced to its wonted density. And then we observed by the help of the above mentioned list of paper, whether we had not included somewhat more or somewhat less than an inch of air ; and in either case we were fain to rectify the error by a small hole made (with a heated pin) in the wax, and afterwards closed up again.

Fifthly, Having thus included a just inch of air, we lifted up the slender pipe by degrees, till the air was dilated to an inch, an inch and an half, two inches, &c., and observed in inches and eighths the length of the mercurial cylinder, which at each degree of the air's expansion was impelled above the surface of the restagnant mercury in the tube.

Sixthly, The observations being ended, we presently made the Torricellian experiment with the above-mentioned great tube of six feet long, that we might know the height of the mercurial cylinder, for that particular day and hour ; which height we found to be  $29\frac{1}{4}$  inches.

Seventhly, Our observations made after this manner furnished us with the preceding table, in which there would not probably have been found the difference here set down betwixt the force of the air, when expanded to double its former dimensions, and what that force should have been precisely according to the theory, but that the included inch of air received some little accession during the trial ; which this newly mentioned difference making us suspect, we found by replunging the pipe into the quicksilver, that the included air had gained about

## MEMOIRS ON THE LAWS OF GASES

half an eighth, which we guessed to have come from some little aerial bubbles in the quicksilver, contained in the pipe (so easy is it in such nice experiments to miss of exactness).

. . . . .

The Honorable ROBERT BOYLE was born in Ireland, County Cork, January 25, 1626, and died in London, December 30, 1691. He made his home in Oxford from 1654 to 1668, when he moved to London. It was while living at Oxford that he invented the air-pump, which was perfected for him in 1658 or 1659 by his assistant in chemistry, Robert Hooke, who was afterwards so famous. In 1663, at the incorporation of the Royal Society by King Charles II., Boyle was appointed by the charter one of the council, as he had been one of the persons to whom the society owed its origin. He was elected president of the society in November, 1680; but on account of "the obligation to take the test and oaths," he felt obliged to decline the honor.

It was in 1660 that he published his first experiments, *On the Spring of the Air*, and in 1662 that he announced the law of gases that bears his name. These experiments were repeated later, by Mariotte in France, and were published by him in 1676.

Boyle published a great many papers in the *Philosophical Transactions*, and was actively engaged in scientific work up to the last years of his life. It is worthy of note that nearly all the common lecture-experiments in hydrostatics and pneumatics are due to Boyle.

# ON THE COMPRESSIBILITY OF GASES AT HIGH PRESSURES

# ON THE COMPRESSIBILITY OF GASES AT HIGH PRESSURES

By E. H. AMAGAT

---

## INTRODUCTORY

IN 1869, when I communicated the results of my first experiments relative to the effect of temperature on the compressibility of a gas, no direct experiments had been made on this subject. It was customary merely to quote Regnault's inferences touching the behavior of carbon dioxide at 100° C. At this temperature, since the density of the gas is sensibly independent of pressure for pressures in the neighborhood of 1 atmosphere, one may conclude that under the conditions stated the gas appreciably follows Mariotte's law. Nevertheless, the inference of Regnault is in need of slight modification. My results proved that at 100°, carbon dioxide, although diverging less from the law than at ordinary temperatures, is quite sensibly divergent; and M. Blaserna showed\* a short time afterwards that the discrepancy arose out of an error which slipped into the numerical calculations of Regnault. Indeed, M. Blaserna arrived at an analogous conclusion himself in a purely theoretical paper published in the *Annales de Chimie et de Physique* in 1865 (t. v.).

In 1872 I made a complete publication† of my researches on this subject, having studied ammonia as far as 100°, sulphur dioxide and carbon dioxide as far as 250°, and air and hydrogen up to 320°.

I then believed that at temperatures sufficiently low all gases

\* *Comptes Rendus des Séances de l'Académie des Sciences*, t. xlix., 1869.

† *Annales de Chimie et de Physique*, t. xxix., 1873.

## MEMOIRS ON

behave like carbon dioxide; but that as temperature increases gases begin more and more to follow the law of Mariotte, finally to depart from it indefinitely in a contrary sense as does hydrogen at ordinary atmospheric temperatures. It follows naturally that nitrogen, which, as I showed, obeys Mariotte's law as far as  $100^{\circ}$  and between 1 and 2 atmospheres, presents a negative discrepancy below that temperature; and that hydrogen more and more highly heated continues to present an invariably negative divergence of increasing value. Experiment, however, has shown me that at  $200^{\circ}$  the divergence of air always sensibly zero does not from the shape of the curves tend to become negative, and that even for the case of hydrogen the discrepancy tends rather to vanish than to increase in the negative direction or to remain negative. Naturally I then inferred that the effect of temperature was an approach of both gases towards the law, the compressibility of the first being diminished and that of the other increased.

It will be seen in the course of the present paper that this conclusion is correct relative to hydrogen, but that for air the interpretation of the results will have to be changed. It will also be seen that it must be impossible to arrive at a knowledge of the general laws for gases as long as the investigations are limited to an interval of pressure within which the trend of the discrepancies hardly even begins to appear; that these laws will not be manifest in their entirety until the experiments are pushed forward throughout several hundred atmospheres; that, finally, all that has hitherto been known about the compressibility of gases would not have enabled any one to even suspect the laws in their true characters, such as I shall establish them below.

I shall not enter into any details as to the formulas by aid of which different physicists have sought to express the effect of temperature on the compressibility of gases. These formulas, as a rule purely empiric, are not applicable except within very narrow pressure-limits; moreover, I shall have occasion to speak of them in the near future in a paper referring specially to low pressures.

During the course of my experiments I was able to show that, even after making allowance for atomic volume, the shortcomings of Mariotte's law cannot be explained fully by postulating an internal pressure tending to move the molecules nearer

## THE LAWS OF GASES

together, because this pressure would be different for the same mean distance of the molecules at different temperatures. I shall return to this point below, and then complete the demonstration by comparing the results at which I have arrived with those predicted by the theory of M. Hirn.

Recently M. Winkelmann has published the results of experiments made with ethylene between  $0^{\circ}$  and  $100^{\circ}$  and between 1 and 2 atmospheres. He finds, corroboratively, that at  $100^{\circ}$  ethylene obeys the law of Mariotte more nearly than at  $0^{\circ}$  C. This is precisely my deduction for all the gases treated up to  $100^{\circ}$ ,  $250^{\circ}$ , and  $320^{\circ}$ .

With the exception of these experiments and those described in the classical memoir of Andrews on the critical point, I believe that no other experimental data are available, barring the results which I adduced in the memoir summarizing my experiments.

As to laws treating of the manner in which the compressibility of a gas is modified at high pressures throughout different temperatures, they are quite unknown. It was, therefore, with the purpose of filling this important gap that I undertook the researches which make up the subject of the present memoir.

I have studied the gases nitrogen, hydrogen, marsh gas, ethylene, and carbon dioxide. As for air, and particularly oxygen, I fear that at the higher temperatures the action of the latter gas on mercury will be too rapid to admit of the necessary measurements, and this in greater degree as the experiments are more prolonged under the conditions of high temperatures stated.

At ordinary temperatures, on the other hand, the experiments can be conducted with relatively great despatch. A series of six determinations may be made with rigor in a quarter of an hour, and then all oxidation is inappreciable. Hence, in my first research I was able to study these two gases (by the method of comparison) without being annoyed by the difficulty in question. It is my object, moreover, to make a special study of it at some other time.

### DESCRIPTION OF THE APPARATUS

The apparatus of which I here make use is the same which has already served me in the determination at ordinary

## MEMOIRS ON

temperatures of the compressibility of the gases air, oxygen, hydrogen, carbon dioxide, marsh gas, and ethylene, in comparison with nitrogen. I have briefly referred to it in my first memoir without giving a full description. However, as on that occasion I entered with considerable detail into the construction of divers parts of this class of instruments, I am able to confine myself to narrower limits here.

Figure 1 shows the apparatus drawn to a scale of one-twelfth actual size. On the right hand is the nitrogen manometer.\* It has the identical dimensions and is mounted in quite the same manner as the one on the machine described in my first memoir on the subject. In this case it was used to measure the compressibility of nitrogen in the Verpillieux mine shaft. The jacket through which the current of water circulates and the enclosed thermometer are attached in the same way. The lid or flange which carries the whole is secured by four bolts to a hollow block of cast-iron, in the cavity of which the reservoir of the manometer is situated. On one side is a small wheel by which a cylindrical plunger, passing through a long box stuffed with leather, may be actuated for the purpose of regulating the applied pressure or of bringing the mercury meniscus in the stem of the manometer upon any division mark determined in advance. This pressure was calculated from the known compressibility of nitrogen.

On the left hand of the figure is another massive hollow block carrying a manometer, within which is the gas to be compared with nitrogen. This part is more bulky than the former, and as a whole similar to the apparatus described in my first memoir. Indeed, the experiments then treated might in any case be repeated with it. The difference lies merely in details of construction, and principally in the disposition of the stop-cocks. Only the right half of this large block is to be used in the experiments with which we are here concerned. The left half of this part of the figure, carrying a lid with three bolts, may be overlooked. In the earlier manometric experiments the lower end of the hollow steel filament which ran to the top of the mine shaft was here affixed. [*See couplings attached.*]

\*In the *Comptes Rendus*, April 12, 1880, I showed that under the influence of pressure applied in the interior only these manometers are not subject to an increase of volume serious enough to make special corrections necessary.

# THE LAWS OF GASES

FIG. 1.—APPARATUS FOR THE COMPRESSION OF GASES AT DIFFERENT TEMPERATURES

## MEMOIRS ON

If the observations are to be made at atmospheric temperatures, the manometer containing the second gas is jacketed in exactly the same way as the nitrogen manometer. If, however, the observations are to be made at higher temperatures, the glass tube with circulating water is replaced by a rectangular trough, or vapor bath, supported on three iron columns, screwed to the lid of the same block of iron which holds the manometer. For this reason the lid is circular and a little too large, jutting out slightly beyond the block to which it is bolted.

The trough was cast of a single piece of brass. On opposed faces it is provided with two long and narrow windows, closed with plate-glass held in place by brass plates suitably screwed to the sides of the trough. The top is closed with a square brass lid, also secured in place with bolts. To this is screwed a vertical condenser, the purpose of which is to liquefy all escaping vapor and to return it to the trough.

The condenser also carries the slide of an agitator or stirring device for equalizing the temperature of any liquid in the trough.

Temperatures may be read off on the thermometer inserted through and supported by the lid. As is seen, the trough is very solidly put together. It could, if necessary, resist great external pressures or be used for experiments *in vacuo*. The glass plates were not fastened with red-lead cement, as is usually done, but the hermetic seal was made by aid of thick plates of vulcanized rubber. I cannot recommend this adjustment too highly, as it is more convenient and more quickly put together than a red-lead joint and much less liable to break the plate-glass windows throughout the limits of temperature within which india-rubber can be employed. With water at 100° this method of sealing leaves nothing to be desired.

The stem of the manometer of crystal glass passes through the bottom of the trough. The joint is easily made by aid of a tubulure and a perforated cork sliding on the stem. It may also be made with a stuffing-box. In the actual experiments I prefer the first method, which is more simple and gives a good hermetic joint when the necessary precautions are taken, the stem of glass being made to pass through exactly at the centre of the tubulure which holds the cork. The trough, being adjustable by aid of double nuts on the columns, easily admits of any desirable change of position. One of the columns carries

## THE LAWS OF GASES

a movable ring-burner, through the centre of which the stem of the manometer passes. The crown of flame thus obtained suffices to heat the liquid in the trough to any required degree.

The two parts of the machine are connected by a short tube of steel. The apparatus on the left communicates with the mercury pump mentioned in my first memoir through a somewhat longer piece of the same steel tubing. As the pump has been already described, it needs no further consideration here.

The two couplings or stopcocks seen near the bottom of the apparatus on the left of the figure serve to put into communication different parts of the apparatus, either with themselves or with the pump, or to interrupt these communications. There is still a third coupling in the extreme left of the figure, but this is not essential in the actual experiments.

The whole apparatus is fixed to a heavy block of wood by aid of flanges of iron, which I have omitted in the figure. The wooden block in turn is secured to a truck with four rollers of cast-iron; this allows an easy motion of the whole apparatus, whose weight is quite considerable. Four strong levelling screws were provided for adjusting the stems of the manometers vertically, giving to the whole mechanism additional stability.

### METHOD OF EXPERIMENTATION

Having partially filled the apparatus with pure and dry mercury, the nitrogen manometer is first installed, and thereafter the second manometer provided with its trough. As the latter piece is very heavy, it would be difficult to adjust it manually without accident. I therefore had a double differential pulley attached to the ceiling of my laboratory, permitting me to accomplish this operation easily and without danger. Having completed the adjustment of the apparatus, mercury is injected by the pump until this liquid shows itself in the stems of the manometers. The stopcock on the left is now closed, while additional pressure is applied through the small hand-wheel, the stopcock on the right being left open.

To begin the measurements, the water in the trough is heated to the temperature selected, and the necessary constancy of temperature is maintained by suitably regulating

## MEMOIRS ON

the flow of gas and the distance of the burner from the bottom of the trough. This operation unfortunately is often very prolonged, particularly at the higher temperatures. During the whole time the stirring device must be kept in uniform action.

When constancy of temperature has been reached, a heavy table of wood is placed facing the apparatus, and two telescopic sights, fixed to the table, are directed to the meniscuses in the two manometers respectively. Thereupon an assistant, by means of the hand-wheel, brings the mercury successively on the division lines of the nitrogen manometer corresponding to the pressures calculated in advance. The observer at the telescopes registers the indications of the two manometers simultaneously with those of the thermometer of the trough and of the jacket of water circulating around the nitrogen manometer.

As to the latter, observation is made very simply by placing a white screen behind the tube, and always bringing the base of the meniscus upon a division mark of the scale. To read the other manometer, a luminous background, preferably the ground-glass globe of a gas-lamp, is placed at some distance behind the posterior window. The reading of the summit of the meniscus is then observed, well marked by its demarcation from the bright field. In estimating volumes with the aid of a prepared calibration-table, allowance is made for this difference of positions of the meniscuses in the readings.

## METHOD OF CALCULATION

The experiments which I have made with the different gases are all comprised between 30 and 420 atmospheres, and between atmospheric temperatures and 100° C.

Each gas was studied in two series of observations. With the first manometer the experiments were carried as far as 100 or 130 atmospheres; with the second I proceeded from 100 or 130 atmospheres as far as 420 atmospheres. In this way too great a reduction of the volume of gas is avoided.

The measurement of pressure given by the nitrogen manometer was also carried out with two pieces of apparatus for like reasons.

This procedure renders the measurement of volume more

## THE LAWS OF GASES

exact, but it has the drawback of presenting difficulties in recording the indications of the two manometers and in reducing them to a single series. I made this reduction by two different methods, corroborating them as I shall indicate below.

The curves representing the results have been constructed as follows: the abscissas are laid off proportional to the pressures, millimetres of length corresponding to meters of mercury; the lengths of the ordinates are proportional to the corresponding values of the products  $pv$  of pressure and volume.

All the isotherms for the same gas at the different temperatures refer to the same gaseous mass; in other words, the manometers, after once being charged with a given gas, were used in the experiments throughout all temperatures without taking the apparatus apart. To record these families of curves as a whole, I made use of the following two procedures: Consider any particular curve. Supposing that the first manometer has furnished the products  $pv$  as far as 130 atmospheres, for example, and the second as far as 120 atmospheres, deduce from the curve constructed up to 130 atmospheres the value of  $pv$  at 120 atmospheres. All the numbers furnished by the second manometer are now multiplied by the ratio of the value of  $pv$  at 120 atmospheres taken from the first curve to that of the same product furnished by the second manometer at the same pressure. This factor, once calculated, is sufficient to co-ordinate the relative curves at all temperatures, on condition, let it be well understood, that the series which are thus co-ordinated have been made with each manometer at exactly the same temperature. These circumstances were always realized to about  $1^{\circ}\text{C.}$ , and the coefficient calculated for one of the curves has always made the others agree. To insure greater accuracy I computed the coefficient for all the temperatures and selected the mean value. Thereafter I proceeded as follows: Suppose the gas introduced successively into the two manometers rigorously at the same temperatures and at the same pressure. It would then obviously be sufficient to multiply all the products  $pv$  furnished by the second manometer by the ratio of the total volume of the first manometer to that of the second. In reality, however, it was necessary to make a small correction, due to the difference of temperatures and of pressures at which the manometers were charged; but this correction was in all cases very small. The coefficients deter-

## MEMOIRS ON

mined in this way agreed with sufficient accuracy with those determined by the first procedure. They were usually found to be equal to about one per cent., and the mean was taken. Frequently the agreement was even within these limits.

Finally the curves drawn to the scale which I have given above were reduced to one-third of their original dimensions, which far exceeded the usual size for publication.

The observations furnished at the nitrogen manometer were reduced in the following way: A table of products  $p_v$  was first prepared by the aid of my earlier researches, in which the initial volume is considered identical with that of the manometer, and the initial pressure that under which it was charged. Therewith a large curve was constructed by laying off volumes along the abscissas and the values of  $p_v$  along the ordinates. From this I deduced the values of  $p_v$  for the volumes corresponding to the scale marks on the nitrogen manometer, up to which the mercury meniscus was forced. Dividing these values by the corresponding volumes deduced from the tables of calibration, the pressure-values sought are obtained. Thus it is supposed that the reading is made at the same temperature as that at which the manometer was charged at normal pressure. Hence the correction relative to the difference of temperature is always very small. I have also computed the pressures by another method, which gave me essentially the same results. To corroborate the whole I placed the two nitrogen manometers simultaneously upon the pressure apparatus, and I thus found that throughout the coincident part of their registry—*i. e.*, between about 100 and 130 atmospheres—they gave the same results to about half an atmosphere.

It has just been shown that in making the calculations needed for joining the curves it is necessary to know at what temperature and at what pressure the manometers were charged with gas. The experiments were so conducted that the small cylinder which ends off the reservoirs of the manometers below was submerged in mercury at the moment at which its pressure and its temperature were identical with that of the atmosphere, although communication with the gas supply had not yet been cut off. While the small cylinder was thus plunged in the mercury bath, it was provided with a small iron thimble, kept in place by suspension from two springs. In this way the manometer could be removed or placed upon

## THE LAWS OF GASES

the apparatus, the efflux point remaining plunged in the mercury within the thimble.

As a general thing, three series of operations were made with each gas and with each manometer. Having thus established the accordance of a large number of series, I selected the one which seemed to have been made under the most satisfactory conditions.

I took every feasible precaution to have the gases as pure, as free from air, and as dry as possible. For the case of carbon dioxide, in particular, the gas was tested even in the manometer at the end of the experiments. The results given below refer to a gas which left a residue of only 5 parts in 1000 in the lower-pressure manometer and 2 parts in 1000 in the other. All the gases, without exception, were first dried in concentrated sulphuric acid, thereafter in a desiccator filled with broken glass mixed with anhydrous phosphoric acid.

### NUMERICAL RESULTS

The numerical results contained in the following tables were obtained from the curves which have already been discussed. For ethylene and carbon dioxide, in which the variations of pressure are exceedingly abrupt, I have given the values of  $pv$  in intervals from 10 to 10 meters of mercury; for the other gases, in intervals of 20 meters only. The first horizontal row shows the temperatures at which the observations were made. The corresponding pressures are contained in the first vertical column.

In case of marsh gas (methane) data are given only up to 300 atmospheres. This gas was actually studied in certain series as far as 420 atmospheres, like the others; but an error appeared in the values of the coefficient for co-ordinating these curves which increased to more than three per cent., and which I have not been able to explain to my own satisfaction. I therefore prefer to give the data of the first series only, which showed sufficient accordance throughout.

The curves given in figures 2, 3, 4, 5, 6, represent these results comprehensively. In those relative to nitrogen, to hydrogen, and to marsh gas a part of the ordinate lengths has been suppressed. It is therefore necessary to reproduce this inferential-ly with the aid of the numbers given at the origin.

## EXAMINATION AND DISCUSSION OF THE RESULTS

An inspection of the curves shows at once that the families may be referred to two extreme and to certain intermediate types. For hydrogen all the lines are appreciably parallel and

## THE LAWS OF GASES

straight at all the temperatures at which experiments were made. This invariability in the form of the curves seems to indicate that this gas has reached a limiting state characterized by their direction. At all the temperatures which I investigated the values of  $pv$  increase in their variation with pressure.

Carbon dioxide and ethylene form the contrasting type. The products  $pv$  at first decrease very rapidly, reach a minimum,

FIG. 2.—ISOTHERMS ( $pv$ ) FOR NITROGEN

and thereafter increase indefinitely. These variations of  $pv$ , very rapid at temperatures near the critical point, show a marked diminution when temperature rises. The point of the curve at which the ordinate is a minimum moves regularly away from the origin, and the locus traced comes out very clearly on inspection of the curves. The minimum seems to move away from the origin less rapidly after passing a certain temperature; after which it apparently retrogrades. At least, this takes place in marsh gas and nitrogen. Now these gases which constitute the intermediate type are at like temperatures much more distant from their critical state than ethylene or carbon dioxide. For the case of nitrogen and marsh gas the displacement of the minimum ordinate appears much less sharply defined than for the other gases, for the reason that when curvature diminishes, the position of this ordinate is much more difficult to determine sharply. I subjoin a table for carbon dioxide and ethylene,

## MEMOIRS ON

showing at what pressure in meters of mercury the ordinate is a minimum at different temperatures :

CARBON DIOXIDE		ETHYLENE	
—	—	16.3°	55 <sup>M</sup>
—	—	20.3	60
35.1°	70 <sup>M</sup>	30.1	70
40.2	80	40.0	80
50.0	98	50.0	88
60.0	115	60.0	95
70.0	130	70.0	100
80.0	140	79.9	105
90.2	150	89.9	115
100.0	160	100.0	120

The curves for carbon dioxide and ethylene may advantageously be considered by themselves for the time being ; because of the larger variations of compressibility involved, they

FIG. 8.—ISOTHERMS ( $pv$ ) FOR HYDROGEN

are more suitable than the others for the demonstration of the general laws of these variations. Let the curves for carbon dioxide be taken first. It is obvious at the outset that at temperatures in the neighborhood of the critical point the initial branches of the curves, or those which precede the minimum ordinate, are concave towards the axis of pressure. The con-

## THE LAWS OF GASES

cavity is well marked, and appears to be prolonged quite into the region of small pressures. This is indicated by the dotted lines which represent the phenomenon approximately, at pressures lower than those at which the experiments began.

To construct these parts of the curve I simply determined

FIG. 4.—ISOTHERMS ( $pv$ ) FOR ETHYLENE

the point of departure corresponding to normal pressure, which was found without difficulty, since I knew the volume of carbon dioxide for the particular pressure and temperature at which the manometer was charged with gas. From this I deduced the volume occupied by the gas, and consequently the value of

## MEMOIRS ON

$pv$ , at the same pressure for all the temperatures, in virtue of the values of the coefficient of expansion of carbon dioxide, given a long time ago in my own papers, for temperatures between  $0^\circ$  and  $100^\circ$  and under normal pressure. Thereupon I joined the points of departure so obtained with the first points of the continuous curves, allowing myself to be guided by their

FIG. 5.—ISOTHERMS ( $pv$ ) FOR CARBON DIOXIDE

general trend. Similar dotted lines were drawn for nitrogen and hydrogen, but not for ethylene and methane, since I lacked data as to their dilatation.

To return from this digression to the general form of the curves, I may point out that the concavity observed in the initial branches which is presented in the case of ethylene,

## THE LAWS OF GASES

occurs also, I might almost say *a fortiori*, in the results which Regnault investigated as far as 28 atmospheres. In fact, these data were obtained at temperatures lower than those from which I started—*i. e.*, lower than  $35^{\circ}$  for carbon dioxide.

The concavity specified vanishes pretty rapidly when temperature rises. At  $50^{\circ}$  C. it is no longer apparent, and the curve only presents the convexity which produces the minimum of  $pv$ .

For gases other than ethylene and carbon dioxide, the concavity has entirely disappeared even at ordinary temperatures. This form of curve for the lower pressures, for the moment at

FIG. 6.—ISOTHERMS ( $pv$ ) FOR MARSH GAS

least, does not command much attention; but it is quite different in those parts of the curves which follow the minimum ordinate, and throughout which  $pv$  increases indefinitely. For temperatures in the neighborhood of the critical point, the curve turns rapidly after passing the ordinate in question, and changes almost at once into a line which is very nearly straight. Some points seem to indicate traces of concavity, so vaguely, however, as to be referable to errors of observation.

As temperature rises the convexity of the curves diminishes very rapidly, and the general aspect of the families of curves shows an unmistakable tendency to slope upward and to change to straight lines throughout their extent. The occurrence of minimum ordinates thus gradually ceases.

## MEMOIRS ON

True, this tendency is indicated clearly only in the isotherms of carbon dioxide and of ethylene. If, however, one calls to mind that hydrogen is at ordinary temperatures in a thermal state, which the two gases specified reach at very much higher temperatures; that for hydrogen the transformation in question is actually complete at ordinary temperatures, continuing in the same sense up to  $100^{\circ}$  without showing the slightest trace of any superimposed deformation; if, finally, one adds the evidence obtained from the curves for methane and nitrogen which make up the intermediate type, then the general features of these gaseous phenomena become strikingly apparent. Indeed, I would insist on this point of view (the consequences of which will be shown below), that not only do the curves straighten out for all gases in such a way as to reproduce the case of hydrogen at sufficiently high temperatures—*i. e.*, in a way to present values of  $pv$  continually increasing with pressure—but that they really tend to become *straight lines* throughout their whole extent.

For hydrogen the occurrence of straight isotherms is as completely verified as the accuracy of the experiments permits up to 100 atmospheres about and from ordinary temperatures onward. At smaller pressures, a trace of concavity seems still to cling to the curves. This is much less discernible at  $100^{\circ}$ , if it be not altogether wiped out.

The concavity of the curves for nitrogen is clearly marked at ordinary temperatures, but it is much less accentuated at  $100^{\circ}$ , where the rectilinear portions are already apparent.

Another fact not less important (as will appear below) is this, that the curves in their rectilinear parts are nearly parallel; parallel in such a way, moreover, that to obtain the general direction of these lines—a characteristic for each gas—it is sufficient to construct one of them near the critical point. Under critical conditions the lines become straight almost immediately after leaving the minimum ordinate. Nevertheless, it would be hazardous to affirm that these lines are absolutely parallel; they seem rather to merge gradually into straight lines, being asymptotic to a direction which differs very little in all the cases for the portion already sensibly straight in the curves constructed.

The endeavor must now be made to unravel general laws relative to the variation of compressibility with temperature.

## THE LAWS OF GASES

We have seen that for each gas there exists a temperature beyond which  $pv$  increases continually with pressure. It is, however, inaccurate to state that with increasing temperature the gas continues to diverge more and more seriously from the law of Mariotte, in the sense of being less compressible. The contrary is the fact. Let the values of the ratio  $\frac{pv}{p'v'}$  be examined between the limits  $p$  and  $p'$  of pressure and at different temperatures. It follows from the parallelism of the lines that in passing from a given temperature to another higher in the scale the values of  $pv$  and  $p'v'$  increase by the same quantity. Hence the value of the ratio increases, since it is smaller than one.

All this is clearly shown in the following table containing values of  $\frac{pv}{p'v'}$  between 100 meters and 320 meters of pressure and at different temperatures:

### HYDROGEN

° C.	RATIO $\frac{pv}{p'v'}$
17.7 .....	0.830
40.4 .....	.838
60.4 .....	.845
80.1 .....	.853
100.1 .....	.856

Thus for increasing temperatures the gas expands more in accordance with Mariotte's law, for the simple reason that the constant difference of the products  $pv$  and  $p'v'$  is added to the greater and greater values of the products. The reason is not that  $pv$  tends to become constant, a result which occurs for no gas whatever.

It is quite certain that, on sufficiently cooling hydrogen, this gas would eventually contract more than the law of Mariotte indicates. On increasing temperature the discrepancy would at first vanish and thereafter change sign. But the divergence, instead of continuing to increase negatively, would reach a maximum value, after which it would begin to approach unity, as is actually the case in the experiments.

## MEMOIRS ON

Let the family of curves relative to carbon dioxide now be examined: They begin at  $35^{\circ}$  C.—*i.e.*, only a few degrees above the critical point. Following the values  $\frac{pv}{p'v'}$  from degree to degree between the pressure limits 100 and 120 meters of mercury, for example, we find the ratio smaller than unity at  $35^{\circ}$ ,  $40^{\circ}$ , and  $50^{\circ}$ . Above  $60^{\circ}$ , on the contrary, the ratio exceeds unity; after this it evidently again becomes smaller as the temperature continually increases, and finally remains indefinitely at a point below this value. Clearly, therefore, the period within which the gas is more compressible than the law of Mariotte asserts may be preceded by a period where it is less so at a lower temperature. The curves also show that a pressure exists beyond which  $\frac{pv}{p'v'}$  is always smaller than unity, whatever be the temperature. If one imagines the locus of the points of minimum ordinates actually constructed, and if the curve has itself a maximum abscissa (I have shown that this is very probable), it is beyond the pressure corresponding to this abscissa that the fact in question becomes manifest.

Approaching the region of lower pressures one observes similarly that a value exists beyond which the primary period corresponding to  $\frac{pv}{p'v'} < 1$  no longer occurs. The value in question is the pressure at which the gas liquefies at a temperature very near the critical point. It is the critical pressure.

All these results are rather complicated, although an inspection of the curves immediately shows them clearly. They may, however, be enunciated in a simpler form. Suppose the family of curves divided into two regions by the curve which is the locus of minimum ordinates. The left-hand area will then comprehend those parts of the curves for which  $\frac{pv}{p'v'} > 1$ ; in the right-hand area, contrariwise, we shall everywhere have  $\frac{pv}{p'v'} < 1$ . In the first region,  $\frac{pv}{p'v'}$  decreases when temperature increases; in the second the opposite is the case.

The following table has been computed from the data for carbon dioxide to substantiate these results. It may be observed in passing that in the second region the effect of temperature diminishes whenever pressure increases.

# THE LAWS OF GASES

## CARBON DIOXIDE

The limits of pressure between which  $\frac{pv}{p'v'}$  has been calculated are inscribed at the head of the respective vertical columns. We may therefore summarize the role of temperature in its effect upon the compressibility of gases by the following laws:

1. For pressures lower than the critical pressure and with continually increasing temperature, the divergence from Mariotte's law, positive at first at sufficiently low temperatures, passes through zero and eventually becomes negative. Beyond a certain negative value, however, the discrepancy diminishes indefinitely without changing sign.

2. For pressures between the critical value and a superior limit peculiar to each gas, the period during which the discrepancy is positive is preceded at still lower temperatures by a period for which it is negative, in such a way that the discrepancy changes sign twice.

3. Beyond the superior limit indicated in the preceding law the discrepancy is negative at all temperatures. It diminishes in general as temperature increases, always excepting those pressures which are too near the limit specified. In these places the variation is more complicated.

4. Beyond a sufficiently high temperature the law of compressibility of a gas is represented by the equation  $P(V-a) = \text{const.}$ , wherein  $a$  is the smallest volume to which the gas can be reduced; in other words,  $a$  is the absolute volume of the constituent matter.

## MEMOIRS ON

The last law virtually states (as will appear below) that beyond a certain sufficiently high temperature all the curves become straight lines.

It goes without saying that the departure from the law of Mariotte here in question refers to pressures arbitrarily chosen within the limits of pressure indicated by the laws.

### DILATATION OF GASES AT HIGH PRESSURES

The data which precede are evidently available for the computation of the coefficient of expansion of a gas, even though the experiments were not specially directed towards this end. True, results so obtained cannot have a degree of precision comparable with those investigated by the ordinary methods at low pressures; but the accuracy will nevertheless be sufficient to point out the general features.

Mere inspection of the families of curves enables us to form a conception of the remarkable variation to which the dilatation of a gas is subject in the neighborhood of the locus of minimum ordinates; above all, at temperatures near the critical point.

If we reflect that for a given pressure the length of the ordinate is at each temperature proportional to the volume of the gas, it follows that the dilatation for each pressure is consequently given by the curves. To arrive at the general facts, however, it is necessary to compare the coefficients of mean expansion at different pressures between the sufficiently narrow limits of temperature. It is with this end in view that I have computed the table which is about to follow.

The coefficients of expansion inserted are the values of  $\frac{v' - v}{v(t - t')}$  between the limits of pressure and of temperature indicated. The volumes were deduced from the curves by dividing the ordinates  $pv$  by the corresponding pressure. It sufficed for this purpose to take the difference of ordinates corresponding to  $t$  and  $t'$  degrees at each pressure, to divide this difference by the inferior ordinate giving  $\frac{pv' - pv}{pv}$  or  $\frac{v' - v}{v}$ , and finally to divide this result by the difference of temperature.

The data thus obtained for carbon dioxide and ethylene follow:

If by running along a horizontal column one endeavors to find how the coefficient of expansion varies with temperature at constant pressure, one observes a rather complex result for the values given in the middle of the table, which correspond to the neighborhood of the locus of minimum ordinates; but if one considers only the extreme regions, regions which correspond to low pressures or to pressures relatively high, it becomes easily manifest that the coefficient diminishes regularly with temperature. Particularly on arriving near the limits of press-

## MEMOIRS ON

ure will it be observed that the expansion is sensibly proportional to the interval of temperature. This is the case with hydrogen at all pressures.

Again, if in a survey of the vertical columns of the tables we endeavor to find the variation of the coefficient of expansion with pressure at a given constant temperature, we encounter a clear-cut law at once. The coefficient is at first seen to increase with pressure up to a maximum value, and thereafter to decrease regularly. This maximum corresponds very nearly to the pressure for which the ordinate is a minimum. If in place of taking the mean coefficient between limits as far apart as  $20^{\circ}$  the temperature interval  $t' - t$  be more and more diminished, the limiting value  $\frac{dv}{dt} \frac{I}{v}$  will coincide as to the pressure position of its maximum with the same pressure which corresponds to the minimum ordinate.

In proportion as temperature increases, this maximum is less and less marked until it eventually vanishes, as in the case of hydrogen. The following table, drawn up for this gas, shows at the same time that the mean coefficient decreases uniformly when pressure increases.

Pressure	HYDROGEN	
	• 17°—60°	60°—100°
40 Meters	.0033	.0029
100 “	.0033	.0028
180 “	.0031	.0027
260 “	.0030	.0025
320 “	.0028	.0024

I may, therefore, summarize the laws relative to the expansion of gases in the following way :

*1. The coefficient of expansion of gases (referred to the unit of volume) increases with pressure up to a maximum value, beyond which it decreases indefinitely.*

*2. The pressure corresponding to this maximum coincides in position with the pressure for which the product  $pv$  is a minimum. Consequently, at this exceptional point the gas accidentally obeys the law of Mariotte.*

## THE LAWS OF GASES

*3. For continually increasing temperatures the maximum in question becomes more and more indistinct and finally vanishes.*

### COVOLUME—ATOMIC VOLUME

We have seen that for hydrogen the curves obtained are nearly straight lines, and that the same is the case for carbon dioxide and for ethylene throughout a considerable part of the region beyond the minimum ordinate. We have seen furthermore that for increasing temperatures the curves tend more and more to become straight lines throughout their whole extent, thus again resembling the phenomenon observed with hydrogen at temperatures above that of the atmosphere. In this case the curves become

$$(1) \quad pv = a p + b.$$

The initial ordinate  $b$  being the value of  $p v$  at the limit—*i.e.*, for a pressure infinitely small, if the laws which we have adduced are true under these conditions. This indeed is a question which has not yet been sufficiently studied and which I shall shortly take up again. We shall therefore regard our inferences limited as to pressures to an interval within which the results present a sufficient degree of certitude. As to hydrogen, I have already stated that for pressures less than 100 atmospheres the line still shows a slight curvature even at 100° C. But it is reasonable to admit that this curvature will quite vanish at temperatures taken high enough, and that the line will become straight—at least, above the pressures in the neighborhood of normal pressure.

The equation (1) may be put in the form

$$(2) \quad p (V - a) = b,$$

$b$  and  $a$  being constants. The result arrived at is therefore this, that at a given temperature the product of the pressure and the volume diminished by a constant quantity does not vary. If furthermore the relation is written

$$(V - a) = \frac{b}{p},$$

it appears that when  $p = \infty$ ,  $v = a$ . That is,  $a$  is the volume which the gas eventually takes when pressure increases indefinitely. This may be rationally interpreted by considering  $a$  as the absolute volume of the matter within the gas, supposing that the molecules will ultimately touch each other, and not the molecules only but the atoms which make up those molecules.

## MEMOIRS ON

Dupré and M. Hirn have reached a similar conclusion within certain limits by different methods, and in a way quite unlike that which I have just explained; but their inferences would lead to interpretations which are at variance with my researches, taken as a whole.

In fact Dupré, from fundamental formulæ in the mechanical theory of heat, which he treats in his work (Dupré, *Théorie mécanique de la chaleur*), deduces the following law which he calls the law of *covolumes*, as an approximation of a higher order of accuracy than the law of Mariotte. I will quote it verbatim:

*“At constant temperature the pressures of a mass of gas vary inversely, as the volumes diminished throughout by a small constant quantity  $c.v_0$ . This is to be called the covolume when the volume  $v_0$  under normal conditions is the unit of volume.”*

For nitrogen, carbon dioxide, and air the covolume of Dupré is positive; for hydrogen it is negative. Seeking a verification of this law by aid of the numerical data in the classical research of Regnault, Dupré found that this was feasible for hydrogen, as may well be anticipated after what has just been said; but for nitrogen, and above all for carbon dioxide, the verification leaves much to be desired. It could not be otherwise, since the law of the covolume presupposes that the curve representing the results in the above co-ordinates is straight. This condition is not realized for the case of nitrogen, nor for carbon dioxide, unless it be for temperatures and under pressures for which the covolume becomes precisely contrary in sign to that deduced by Dupré. The law of the covolume with the interpretation given to it by this physicist cannot therefore be admitted.

M. Hirn has published an elaborate research\* on the same subject. Endeavoring to interpret the variations from the law of Mariotte, he points out that even if the molecules of a gas exert no reciprocal action on each other the gas cannot rigorously obey this law, since the variable part of the volume is not the total volume of the gas, but rather the latter diminished by the volume of the atoms. This is equivalent to admitting the quantity  $\alpha$  defined above. M. Hirn contends that it is merely the variable part of the volume which ought to enter into the expression of Mariotte's law, a conclusion far from evident.

For the case in which one may not neglect the interactions

\* Hirn : *Théorie mécanique de la chaleur*, t. ii.

## THE LAWS OF GASES

of the molecules, M. Hirn introduces an internal pressure to be added algebraically to the external pressure, and the general expression of the law for constant temperature becomes

$$(P + p) (V - a) = (P' + p') (V' - a),$$

$p$  and  $p'$  being the internal pressures corresponding to the volumes  $V$  and  $V'$ . For hydrogen  $p$  and  $p'$  would be approximately zero, whence

$$P (V - a) = \text{const.},$$

an expression which M. Hirn verifies by aid of the data of Regnault.

For nitrogen this correction of volume becomes insufficient, and does not even retain the same sign. It is therefore necessary, in order to explain the variation of this gas, to admit an internal pressure of marked value. Now if this is the case with nitrogen for pressures less than 20 atmospheres, one cannot assuredly deny that it must also be the case for hydrogen when this gas is reduced to the three-hundredth part of its volume. But for pressures as large as 430 atmospheres, and very certainly even for higher pressures, the law for the compressibility of hydrogen is given by the equation

$$p (V - a) = \text{const.}$$

as rigorously as for smaller pressures. The internal pressure is therefore zero. Furthermore, if we examine the data relative to carbon dioxide and ethylene, we again observe that for temperatures near the critical point a large part of the curve becomes straight. This takes place for carbon dioxide at 35° from 100 to 430 atmospheres; and the same phenomenon is observed at 18° C. between the same limits of pressure, even though the body is now a liquid—*i.e.*, has been subjected to what is properly termed liquefaction. Under these conditions the compressibility of the gas is thus represented by the relation

$$p (V - a) = \text{const.},$$

and  $a$  has the same value as at 100° C., and higher temperatures where the same formula represents the phenomenon from the lowest pressures upward. Hence one may argue that under circumstances in which the internal pressure ought to attain a very large value (at 35° between 100 and 400 atmospheres), this pressure would actually vanish from the equation; whereas it would show a preponderating influence between normal pressure and 100 atmospheres, where it ought itself to explain the *greater part of the variation of volume.*

# MEMOIRS ON

I have already shown that, even after making full allowance for the atomic volume, the occurrence of an internal pressure in such a way as to represent a mere addition to the external pressure is quite insufficient to give an account of the variations from Mariotte's law. The demonstration was on that occasion based on numerical differences of rather small value. To-day, with the new results which I have reached, I am able to make this fact much more evident. I will therefore take up the demonstration again and complete it, introducing in its turn the atomic volume.

Let  $V$  be the volume of the gas at the pressure  $P$  and the temperature  $T$ ; let  $\alpha$  be the corresponding atomic volume; let the gas be compressed as far as pressure  $P'$ , and let  $V'$  be the new volume at the same temperature. Hence one obtains

$$\frac{(P+p)(V-\alpha)}{(P'+p')(V'-\alpha)} = 1, \quad (1)$$

$p$  and  $p'$  being the internal pressures for the volumes  $V$  and  $V'$ .

Now let the gas be heated as far as  $T'$  degrees and let  $P_1$  be the pressure needed to keep the volume at  $V$ . The internal pressure, if it depends only on the mean distance apart of the molecules, will again be  $p$ .

Compress the gas until its volume has diminished to  $V'$  and let  $P_1'$  be the pressure needed for this purpose. The internal pressure will again be  $p'$  for the reason specified. Hence we should obtain :

$$\frac{(P_1+p)(V-\alpha)}{(P_1'+p')(V'-\alpha)} = 1. \quad (2)$$

Equations (1) and (2) may be put under the following form :

$$(3) \quad \frac{P(V-\alpha)}{P'(V'-\alpha)} = 1 + \frac{p'(V'-\alpha) - p(V-\alpha)}{P'(V'-\alpha)};$$

$$(4) \quad \frac{P_1(V-\alpha)}{P_1'(V'-\alpha)} = 1 + \frac{p'(V'-\alpha) - p(V-\alpha)}{P_1'(V'-\alpha)}.$$

$$\text{Put} \quad \frac{p'(V'-\alpha) - p(V-\alpha)}{P'(V'-\alpha)} = a, \quad (5)$$

$$\text{and} \quad \frac{p'(V'-\alpha) - p(V-\alpha)}{P_1'(V'-\alpha)} = a'. \quad (6)$$

The relations (3) and (4) now become :

$$\begin{aligned} \frac{P(V-\alpha)}{P'(V'-\alpha)} &= 1 + a, \\ \frac{P_1(V-\alpha)}{P_1'(V'-\alpha)} &= 1 + a'. \end{aligned}$$

## THE LAWS OF GASES

Here  $a$  and  $a'$  are the variations from Mariotte's law, after the correction for atomic volume has been applied; in other words, the discrepancy of the law:

$$p(V-a) = \text{const.}$$

Furthermore, by dividing (5) by (6):

$$(7) \quad \frac{a}{a'} = \frac{P_1'}{P_1}.$$

Hence the departure from the law  $P(V-a) = \text{const.}$  must be in the inverse ratio of the corresponding final pressures  $P_1$  and  $P_1'$ .

As an example, data may be given for carbon dioxide at  $35^\circ.4$  between the pressure limits 30 and 70 atmospheres. From the isotherms one finds at once that at pressures of 40 and 220 atmospheres at  $100^\circ$  the gas has the same volume as at 30 and 70 atmospheres at  $35^\circ$ .

$$\text{Hence} \quad \frac{a}{a'} = \frac{220}{40}.$$

The volumes  $V$  and  $V'$  are given in turn by the ordinates corresponding to 30 and 70 meters of mercury. It suffices to divide these by the corresponding pressures. The value of  $a$  is deduced from the straight part of the curves of which it is the angular coefficient. Thus without difficulty

$$V = 7.9, \quad V' = 1.03, \quad a = 0.625.$$

Hence one should have

$$\begin{aligned} \frac{(7.9 - .625) 30}{(1.03 - .625) 70} &= 1 + a, \\ \frac{(7.9 - .625) 40}{(1.03 - .625) 220} &= 1 + a', \end{aligned}$$

whence, after reduction,

$$\begin{aligned} a &= 5.65, \\ a' &= 1.81. \end{aligned}$$

Finally, in accordance with equation (7),

$$\frac{5.65}{1.81} = \frac{220}{40} \text{ or } 3.12 = 5.5,$$

an absurdity out of all proportion with such discrepancies as might arise out of mere errors of experiment, even when the approximate method of verification is taken into account.

The so-called internal pressure cannot therefore be admitted into gaseous kinetics in so far as this pressure is to depend only on the mean distance apart of the molecules—*i.e.*, to be a

## MEMOIRS ON

function of volume only. It is also a function of temperature, as M. Blaserna\* has already inferred elsewhere.

In his calculations of the internal work of a gas M. Hirn makes frequent use of internal pressure. The results at which he thus arrives may therefore appear discordant with my own results. Without wishing to enter into a detailed discussion, I will remark that this disagreement can only be apparent; it is due simply to the fact that rather in the interior of the molecule than between integrant molecules is the larger part of the internal work expended. It does not follow that the values of internal work numerically calculated are erroneous.

M. Clausius has evolved a theory which has since become classic, and which can very easily give an account of the discrepancies of Mariotte's law. This theory, which in its inception is traceable to Bernoulli, and the first kinetic explanation of Mariotte's law to Krönig, interprets pressure as due to the impact of the molecules of a gas on the walls of the vessel holding it. Pressure thus depends on the kinetic energy of the translational motion.

When a gas is compressed at constant temperature, it suffices to assume that a part of the translational or intermolecular energy is transformed into intramolecular energy or into the energy of molecular rotation, to give a complete account of the discrepancy of Mariotte's law. For the result would be a diminution of  $p v$ . As the effect of atomic volume would make the law deviate in a contrary sense, one is led to anticipate the differing phases through which the compressibility of a gas passes, according as one or the other of the two causes supervenes. It is even possible that both causes may annul one another, and that the gas thus accidentally obeys Mariotte's law, as is the case, for instance, in the region of minimum ordinates.

Taken as a whole, the results which I have reached show pretty clearly that a special theory for gases and another for liquids is out of the question. Consider, for example, the isotherms of hydrogen: how is it possible to admit one theory to explain the facts represented by one part of the curves and another theory to explain the rest, seeing that their form shows

\* Blaserna : *Comptes rendus*, t. lxi., 1869.

## THE LAWS OF GASES

conclusively that a phenomenon of perfect continuity has been observed? Now the theory of impact cannot be applied to hydrogen under 400 atmospheres, since under these conditions the proximity of its molecules would make it rather a liquid than a gas. As long as questions on the condition of carbon dioxide or of ethylene at ordinary temperatures are uppermost, one may infer that the two parts of an isotherm situated on each side of the minimum ordinate are subject to the different laws; inasmuch as an abrupt variation, which may reasonably be interpreted as limiting two different thermal states, separates them. But this is no longer applicable when the gases are subjected to higher temperatures, nor for hydrogen (as I have stated) even at ordinary temperatures.

It is very remarkable that the law given by the equation  $p(V-a)=\text{const.}$ , which has been the immediate outcome of my experiments, and which appears to be the limiting law towards which all gases converge when their temperatures are raised, is the same law which is in action in the neighborhood of the critical point, whenever the compressibility of a body is considered throughout increasing pressures. Thus it is rather a law for the liquid than for the gaseous state. I will even add that it is specifically the law of liquids—at least, within the limits of actual experimental inquiry; for it appears from the group of isothermals that carbon dioxide at  $18^\circ$ , which is then truly liquid, follows exactly the same law. Its curve is a straight line whose angular coefficient is  $a$ . Thus we arrive at a result which appears at first sight quite paradoxical, that elevation of temperature transforms the gas into the state of a perfect liquid; and that the region of branches of the isotherms situated on the left of the line of minimum ordinates, the region which corresponds accurately to the gaseous state in the ordinary sense of the word, is a period of turbulence terminating in the phenomenon of liquefaction properly so called. This phenomenon disappears when temperature rises indefinitely and the body becomes a perfect fluid, to employ a word which is at once applicable both to the liquid and the gaseous states.

The state in question is defined by the simple equation  $p(V-a)=\text{const.}$ , or  $pW=\text{const.}$ , if  $W$  is the interatomic volume. The law thus expressed is so very simple that one is naturally induced to seek an explanation for it depending sim-

## MEMOIRS ON

Perhaps I ought to add, in order to escape an unfavorable issue, that the ether taken into consideration here is that only which is retained by and condensed around the molecules in the form of a molecular atmosphere. The ether which is not so condensed but pervades the molecular spaces, whatever be the distance apart of the molecules, is without relevant influence. This does not oppose any reaction, and for it the walls of the vessel do not exist.

The hypothesis which I have just formulated thus renders a natural and complete account of the details of the phenomena brought out by experiment. It does not exclude those kinetic theories which have gained general acceptance among physicists. So far as I can see, it is not at variance with any established experimental fact. It restricts the limits within which the theory of impact is apparently applicable by establishing a transition from the liquid to the gaseous state, which may be passed continuously and the mechanism of which is easily intelligible. Finally, it introduces no difficulty whatever into the phenomenon of liquefaction properly so called.

I have already stated that the law  $PW = \text{const.}$ , which appears to be the general law for fluids, is applicable to liquid carbon dioxide below the critical point, as is evidenced by the straight isotherm for  $18^\circ$  contained in the family of curves. I endeavored to verify the same fact with several liquids, notably with chlorhydric ether, for which I published the compressibilities as far as  $100^\circ$  and 37 atmospheres several years ago.\* The law was reproduced with a very fair approach to accuracy; but in order that these verifications may not be over-estimated, it is well to insert the following remark: If the liquid were quite incompressible its isotherm would necessarily be a straight line, for the ordinate would vary proportionally to  $p$ ,  $v$  being constant. For liquids in general, therefore, inasmuch as they are nearly incompressible, their curve must differ exceedingly little from a straight line, no matter what may be the true law of compressibility. It is thus impossible to derive any very certain inferences from the behavior of the greater number of liquids. For liquid carbon dioxide, however, the case is altogether different, and, *a fortiori*, for hydrogen between limits of pressure as far apart as those within which I have operated.

\* *Annales de Chimie et de Physique* (5), t. xi.; *Mémoire sur la Compressibilité des Liquides*.

## THE LAWS OF GASES

I have still to give the numerical values of atomic volume, having calculated it for hydrogen, carbon dioxide, and ethylene, all of which contain the straight parts of the isotherms clearly defined and of marked extent. In computing the limiting directions of the lines for the other gases, one is liable to make a considerable error.

To obtain  $\alpha$  it is adequate to establish the relation

$$p(V-\alpha) = p'(V'-\alpha)$$

between two pressure values sufficiently far apart and comprehending a part of the curve sensibly straight. Thus the value of  $\alpha$  is deduced from  $p, p', v, v'$ , given by experiment. Hence one obtains the atomic volume of the mass of gas subjected to the experiments from which the curves were constructed. This mass is defined by the normal pressure and the temperature at which the manometers were charged with gas.

I have preferred to refer the atomic volume to the unit of volume of the gas at  $0^\circ \text{C}$ . and 76 centimetres of mercury, obtaining the following values :

Hydrogen .....	0.00078
Carbon dioxide .....	0.00170
Ethylene .....	0.00232

Finally, I may remark that the interpretation given for the value of  $\alpha$  is independent of the hypothesis on which the theory of the gaseous state is founded. It will readily be seen that it is enough that the curves of compressibility should tend to become straight lines in the limit; for under these conditions

$$pv = \alpha p + b, \text{ or } V = \alpha \text{ for } p = \infty.$$

No matter to what theory one may subscribe, therefore,  $\alpha$  appears as the smallest absolute volume which the matter can occupy. One naturally infers that this is the atomic volume. This remark is particularly applicable to hydrogen, the isotherms of which are practically straight throughout their whole extent. For the other gases the determination of  $\alpha$  rests on the inferences deduced from the curves as a whole, but less certainly. The results are therefore given with less assurance.

To pursue this subject exhaustively within the limits which I have set for myself, it will still be necessary to study the compressibility under conditions of pressure lower than those

## MEMOIRS ON THE LAWS OF GASES

occurring in the present research. These experiments will be made directly with an open manometer. I hope to carry the measurements as far upward as  $300^{\circ}$ . I hope also to trace the phenomena further into the region of extremely low pressures—a few millimetres, for instance—on which subject I have already published\* an introductory paper.

Returning again to these experiments, I shall be in a position to add many material improvements to the method which I formerly employed, and above all to the apparatus. They will be completed, I hope, in the course of the next academic year.

PART I.—METHODS OF MANIPULATION

INTRODUCTION

IN the Memoir which I publish to-day I have brought together the whole of my researches on the expansion and compressibility of fluids,\* in so far as they have occupied me during the last ten years. A part only of the results has been published in the *Comptes Rendus de l'Académie des Sciences*; the experimental portions, moreover, were sketched with the utmost brevity compatible with clearness.

The present researches for gases are a direct continuation of my earlier work on the same subject. In the latter the limits of pressure and of temperature employed were too narrow, and the number of isotherms mapped out not great enough to reveal certain relations which appear very clearly in the present results. Such are, for example, the form of the isotherms in the region of the critical point which lay beyond the limits of my first group of curves; furthermore, the contours of these

\* The parts of this great memoir referring to liquids will not be included in the present translation.

## MEMOIRS ON

curves in the region lying to the right of the locus of minimum ordinates, and in which the isotherms under very great pressure seem to merge into straight lines, etc.

As for liquids, the question was virtually untouched when these researches were begun. The increase of the coefficient of compressibility with temperature had been observed for some liquids, together with the contrary effect for water. I myself extended these results, in a memoir published in 1877, to a large number of liquids, and within limits of pressure and of temperature beyond any which had been applied at that time; but the laws as a whole were yet to be investigated, the determination of pressure coefficients was not even attempted, the data relative to the variation of the coefficient of compressibility with pressure were altogether contradictory. Well-known treatises of physics even to-day contain errors in relation to this subject which surpass the limits of plausibility. Since that time, however, several important researches bearing on these phenomena have been published outside of France.

The researches which I am about to describe have been made with a view towards reaching the highest attainable pressures, both for liquids and for gases. It is my purpose, furthermore, to make special investigations for the low pressures—*i.e.*, for the first one hundred or two hundred atmospheres, and thereafter to co-ordinate them in such a manner as to give a complete presentation of the phenomena. Experiments devised to reach a thousand or several thousand atmospheres must at lower pressures of necessity show an inferior degree of accuracy than may be reached in experiments specially adapted to the latter. Circumstances have not permitted me to terminate this research, but the most difficult part of it is finished.

In this place I may be permitted to say that the instruments which are to be described, as well as all others used in my researches for upwards of fourteen years (1877 to 1891), were constructed, in the workshop attached to my department (*service*) at Lyons, by M. Gianotti (at present instrument-maker in Lyons). My tasks have, throughout, been singularly facilitated both by his skill in construction and by the earnestness with which he aided me in the experimental work.

Glass apparatus was made by M. Alvergnyat, or by his successor, M. Chabaud. Indeed, all the apparatus, either of ordinary or of cut glass, which has been used in my experiments

## THE LAWS OF GASES

for twenty-five years or more, was constructed by these gentlemen. I need not further advert to their services, cheerfully rendered in the cause of science.

I shall first describe the methods and the apparatus. They are of like construction, both for liquids and for gases, except as to the piezometer containing the fluid and the manner of charging it. I shall begin with the apparatus for pressure measurement.

### METHODS OF EXPERIMENTATION

#### *The Measurement of High Pressures—"Manomètre à Pistons Libres."*

When I undertook the present researches there was no instrument available for the accurate measurement of pressure beyond the range within which it was customary to compare the well-known empiric pressure-gauges with the open manometers. In practice closed gas manometers are subject to serious inconveniences. Moreover, they cannot be employed above 420 atmospheres, this being the upper limit of the measurements which I made, in 1878, with an open manometer in the shaft of the mine at Verpilloux.

The principle of the instrument improperly called *manomètre de Desgoffe*\* solves the question theoretically; but the practical construction adopted was actually so defective that no reliance could be put on its indications. The manometers of the valve or plug type may perhaps render service in certain cases. M. Marcel Deprez has improved them by replacing—for the first time, I believe—the valve by a free plunger (*piston libre*), which does not allow water to pass except with extreme slowness. But these instruments even when perfected are not available in researches which cannot well be conducted without a pressure-gauge of continuous registry.

The grave difficulty in the way of a realization of Gally-Cazalat's idea is this: to make the pistons perfectly free to move while at the same time obviating leakage. For the large piston the difficulty is in a certain measure solved by the ad-

\* This instrument was invented by Gally-Cazalat; constructed at first by Clair, then by Bianchi, and finally by Desgoffe.

## MEMOIRS ON

dition of an india-rubber membrane. Nevertheless, this ingenious device is not quite beyond criticism; for in the first place the sectional surface is badly determinable, while in the second the action of the membrane gives rise to an error which the operator must either endeavor to estimate or to obviate. In the first instruments which I constructed I retained the membrane design, but an index rigidly attached to the large piston enabled me to follow its motion, and, therefore, that of the membrane also. It was then my purpose to provide the apparatus with a regulating pump, which by injecting a variable quantity of liquid below the membrane would enable me to keep it always in the same horizontal plane, thus suppressing nearly completely the action referred to. Later I found it more advantageous to do away with the membrane altogether and to leave the large piston entirely free.

To secure freedom from leakage, I found it sufficient to give the piston a suitable thickness and to replace the actuating water by a lubricating and at the same time slightly viscous liquid; castor-oil is very serviceable for this purpose.

The analogous difficulty remained for the case of the small piston, which, experiencing strong pressure in a leather-lined stuffing-box, moved only with difficulty and by jerks. It was necessary to make this piston free, like the first, but the condition of no leakage was here very much more difficult of attainment in spite of the small section. For while the large piston receives only the relatively small pressure of the counterpoising column of mercury, the enormous total pressure which is to be measured bears down upon the small piston. I succeeded, however, in meeting the present difficulty by the identical artifice—*i.e.*, by using a sufficiently viscous liquid, in this case molasses. Nevertheless, the function of this body is somewhat different from that of the castor-oil: for while the oil continually lubricates parts, oozing with extreme slowness between them in a way not to interfere with effective action, the molasses penetrates the space around the piston—supposed to be well oiled in advance—with very great difficulty even at very high pressures. When the molasses has succeeded in penetrating and removing the oil, the apparatus still functions, although with loss of some of its original sensitiveness. It is then preferable to detach the small piston and to clean it. When the apparatus has been adjusted with care, it is sufficient to place

## THE LAWS OF GASES

an object of even insignificant weight on the large piston to produce a corresponding small ascent of the column of mercury. The small piston is in general less sensitive, above all after the molasses has penetrated between it and the socket. Finally I succeeded in quite annulling the resistance due to friction by impressing on both pistons a slight movement of rotation. An analogous artifice has long been employed by

FIG. 1.—FREE-PISTON MANOMETER (*Manomètre à Pistons Libres*).

M. Bourdon to overcome the friction of the piston of the apparatus used in standardizing his spirals; but while the leather-lined stuffing-box requires a rapid movement of rotation in order to obviate the friction of a tight fit, my apparatus needs only a slow and slight angular displacement of the pistons in order that the column of mercury may at once take its definite position of equilibrium.

Fig. 1 gives a section of the apparatus. The liquid transmitting pressure arrives by the tube, *c*, through a channel in the

## MEMOIRS ON

piece of steel, *b*, screwed to the brass\* lid, *a*. This piece secures the socket of tempered steel, *d*, holding it down free from leakage by aid of round leather washers. The small piston, also of tempered steel, moves up and down in this socket. The parts are so fashioned that a small chamber, *OO*, is left below *b*. Into this the charge of molasses is to be put. The lower end of the small piston abuts against a small plane of tempered steel, which is seen in the figure, screwed to the centre of the large piston, *P*. A valve-screw, *d'*, may be raised to admit of the escape of air from below in adjusting the apparatus. Circular grooves are cut equatorially around the outer walls of the large piston. The oil accumulates in these channels during its upward leakage, and finally reaches the hollow part or cup of the large piston. The latter moves up and down in a massive envelope, also of brass. This is screwed down to a heavy trough of cast-iron, serving as the base of the apparatus, by a crown of square-headed bolts, and further secured to the lid, *a*, of the apparatus by a second crown of longer bolts. A key, not shown in the figure, may be attached to the large piston at its centre, for the purpose of withdrawing or of inserting it. In such a case the key replaces the small plane of steel.

On the right side of the figure, and screwed to a lateral projection of the trough, is the steel coupling carrying the glass tube in which the mercury column rises. This coupling consists of two parts: the lower part carries a stopcock, and thus the operator is able to remove the glass tube, even when the trough is charged, without spilling the mercury within it. At the left of the figure, and symmetrically placed, is the regulating pump, and this, for a reason similar to the one just given, also consists of separable parts with a stopcock in the lower. The channel by which the oil, *H*, is injected is prolonged by a tubulure extending upward much above the mercury surface, *M*, in order that this may under no condition reach the pump, which is of brass, and thus in danger of amalgamation.

The angular movement of the two pistons is produced by the steel rod, *m m'*, screwed † to the prolongation of the small pis-

\* In the case of instruments for measuring very high pressures, the strength of the brass bolt crown is insufficient; the central part of the lid, as shown by the dotted lines, should be made of steel.

† For pistons of very small diameter, this prolongation is enlarged and different in form.

## THE LAWS OF GASES

ton. This rod passes between two pins, *i*, screwed to the margin of the large piston, and leaves the apparatus through a window in the upper part of the cylinder. Thus both pistons may be put into the same horizontal angular motion, which is transmitted by a simple arrangement not shown in the figure. The regulating pump makes it possible to keep the stem, *mm'*, at a height such as will not interfere with the upper or lower edge of the window. Moreover, by an inverted action of the appurtenances of the manometer, the pump may be made to produce very considerable pressures above the small piston and in the space where the bodies subjected to experiment are placed; it is often convenient to make use of this method to regulate the pressure at the moment of measurement. M. Vieille \* has recently made a very happy application of this artifice, in connection with his studies on the behavior of the crushing manometer (*manomètre-crushers*).

If well constructed, my apparatus will give pressure-values of remarkable uniformity, the accuracy of which depends only on the sectional ratio of the two pistons. The sensitiveness can be increased at pleasure by increasing the value of this ratio and making use of a graded series of pistons. The apparatus which I used was provided with two large pistons, the one 6 centimetres and the other about 12 centimetres in diameter, together with a series of small pistons, the smallest being 5.527 millimetres in diameter.

The absolute error is about the same throughout the whole scale of pressures. The relative error would become intolerably large if a few atmospheres only were to be measured, which, however, is beyond the purposes of the instrument. It is, nevertheless, my intention to construct a small model specially designed for the lower order of pressures, and I hope to find it relatively quite as reliable.

On several occasions I made comparisons of data for the same pressures furnished simultaneously by two different free-piston manometers, or when one of these was replaced by a closed gas manometer. The agreement of the former was always very satisfactory, but this was usually less so with the gas manometers. I do not hesitate to ascribe these discrepancies to the difficulty of manipulating the latter. Here is the com-

\* *Mémorial des Poudres et Salpêtres*, v.

# MEMOIRS · ON

parison of the free-piston manometer which I constructed in 1885 for M. Tait, with two nitrogen manometers and an air manometer. Pressures are given in atmospheres.

TABLE 1.—MANOMETERS

NITROGEN	PISTON	NITROGEN	PISTON	AIR	PISTON
226 Atm.	224 Atm.	102 Atm.	103 Atm.	217 Atm.	215 Atm.
278 “	275 “	154 “	154 “	262 “	263 “
328 “	326 “	213 “	215 “	305 “	306 “

The agreement of piston and gas manometers improves when the latter are used under the best conditions.

In Table 3 are the results of a comparison with an air and a nitrogen manometer, devised for very high pressures, much more sensitive than the above, and directly graduated for each gas by comparison with a column of mercury in one of the

## THE LAWS OF GASES

towers of the Fourvière cathedral in Lyons—that is, under the best conditions possible. The free-piston manometer was itself so adjusted that fractions of an atmosphere were easily read off.

TABLE 3.—MANOMETERS

AIR	PISTONS	NITROGEN	PISTONS	OPEN MANOMETER	PISTONS

Finally, in the last two columns, the table contains a comparison, throughout a few atmospheres only, with an open mercury manometer, the errors of which may be regarded practically zero. The discrepancy is obviously inadmissible for pressures as small as these; but for higher pressures, 50 or 60 atmospheres for example, the absolute error not becoming larger, the results are exceedingly satisfactory.

For the series of measurements reading upward as far as 3000 atmospheres, I chose a pair of pistons such that one atmosphere was equivalent to 1.601 millimetres of mercury at 0° C. For the series limited by 1000 atmospheres, the equivalent height was 4.99 millimetres. In each case I selected those sectional ratios which gave me the highest attainable sensitiveness for the case of a column of mercury 5.20 metres in height, the maximum elevation at my disposal.

### 2. APPARATUS FOR EXTREMELY HIGH PRESSURES

#### *Method of Electrical Contact.*

The methods of which I made use in my preceding researches do not admit of being carried much above 400 atmospheres. It is very difficult to obtain glass tubes which will resist interior pressures more intense than this. To solve this difficulty by plunging the piezometer bodily into a stronger

## MEMOIRS ON

cylinder, necessarily metallic and opaque, presents grave difficulties in regard to the reading of volumes. Otherwise it is the method of Oersted. The difficulty in question was first avoided by means of gravitational apparatus, or by covering the interior of the stem of the piezometer by a film which is dissolved by the liquid transmitting the pressure, thus indicating the height to which it has been raised. These procedures have two serious defects: aside from the fact that they merely give the maximum of the height to which the liquid has been raised, they are quite impracticable for the construction of a regular series. They have given rise to very grave errors. The method pursued for gases by Natterer, which consisted in compressing a known volume of gas into a given space, repeating the operation a great number of times and determining the pressure corresponding to each accession, is certain to be surrounded with great difficulties, and rapidly becomes quite impracticable if one endeavors to raise the temperature. The work of Natterer is none the less extremely remarkable, particularly if the time when it was done (1851) is called to mind. It is hard to explain why it has remained so long unknown in France.

At the time when I began these researches—that is, about 1882—M. Tait was engaged with a study of the compressibility of water, and he called my attention to the method of electric contacts which he employed in his researches. Among other things, I had also thought of this artifice, but I had as yet made no trial of it. Upon the recommendation of the eminent physicist I tried it at once; and since then I have employed no other method, either for liquids or for gases, in all series of measurements carried to the highest attainable pressures and at temperatures not exceeding 50°.

Fig. 2 gives a sectional elevation of the apparatus constructed for these researches. The receiver, or barrel,  $GG$ , in which the piezometer is placed is a cylinder of steel 3 centimetres in diameter internally, and surrounded by a steel jacket,  $G'G'$ , to a point about as far down as the bottom of the aperture within. The total outer diameter is 18 centimetres, the available depth of the receptacle below the position of the upper junction is about 88 centimetres. The somewhat excessive prolongation of the unjacketed breech has a special purpose to which I shall refer below. Pressure is transmitted by a charge

## THE LAWS OF GASES

of water injected by a force-pump, and enters at *D* by way of the valve-coupling, *E*, screwed to the upper part of the receiver on the right. When the pressure attains a certain value de-

FIG. 3.

FIG. 4.—PIEZOMETER FOR LIQUIDS.

## MEMOIRS ON

pending on the upper limit which is to be reached, the screw-valve is closed, and compression is thereafter continued with the use of the device screwed to the head of the receiver. The central piece, *A*, is pierced by an aperture 16 millimetres in diameter, in which a cap-shaped leather washer, *C* (drawn in larger scale at the side), moves up and down. This washer has the form of a little cylinder with a flat base. It is pushed forward by a rod of steel, *P*, advancing with slight friction and terminating in a cone at its upper end. Here the motion is impressed upon it by a steel screw, *V*, the threads of which are 2 millimetres apart and move in a nut of brass carried by a second hollow cylinder of steel, *B*, surrounding the central piece, *A*. This second cylinder is screwed to the jacketed receiver, against which it presses the central piece, *A*, making a pressure-tight joint with it by the aid of a leather washer. The screw is actuated by a four-armed lever seen at the top of the apparatus. At the left, on the same level with the influx valve, there is a special attachment, *F*, of steel, adapted to carry the electric current into the piezometer, insulated from the body of the apparatus. This is attained by aid of a small cone of steel, *K*, preliminarily inserted into the channel within the piece, *F*, and which is wedged after having been surrounded by a very thin, small conical shell of ivory, *OO*, insulating perfectly. Moreover, the taper of the cone is so directed that the internal pressure will force it into more intimate contact with its surroundings. The small steel cone joins the ends of the conducting wires, which are screwed into it in the manner detailed in the enlarged figure. This attachment has never shown the least trace of leakage.

On a level with the influx valve and the attachment, *F*, there is still a third coupling, not shown in the figure, which puts the barrel in connection with the manometer (these three pieces are in reality placed so as to divide the circumference of the cylinder into three equal parts). The connecting tube is about 2 meters long and made up of three parts bored at the lathe, the last piece being afterwards bent down by forging. I at first employed thick tubes of drawn steel, but they burst at about 2000 atmospheres.

The piezometer containing the fluid to be compressed is of a form shown separately in Fig. 3 for gases and in Fig. 4 for liquids. The stem carries a series of fine platinum wires laterally

## THE LAWS OF GASES

inserted into the glass and reaching as far as the middle of the bore. Between each thread there is inserted an electric resistance wrapped around the tube. These resistances are made up of wire covered with india-rubber, and a small part of each coil is exposed so as to be soldered to the corresponding ends of the platinum wires. The whole is then covered by a wrapper, insulating perfectly even when plunged in mercury, and remaining sufficiently soft to insure an equal compression of the glass on opposite faces. When the piezometer is placed within the barrel, the upper terminal is joined to the prolongation seen within the cone of the attachment, *F*, contact being thus completed throughout. When the mercury into which the lower end of the piezometer is plunged rises in the tube conformably with the increasing pressure, and just touches the first of the lateral platinum wires, the current may be closed between any part of the barrel or its metallic appurtenances and the conductor joined at the outer end of *F*.

The jacketed part of the barrel is further enveloped by a spacious brass cylinder filled with ice or charged with water kept in circulation and issuing from special auxiliary apparatus adapted to secure constancy of temperature between 0° and about 50° C. Entering near the bottom, the circulating water issues from a tubulure near the top. A thermometer shows its temperature. Two stopcocks, seen at the bottom of the water-jacket, facilitate influx. The bath is surrounded with wood sawdust, contained between the four braced timbers of oak, and kept in place by shutters not shown in the figure. The upper part is protected with felting.

*Details of Manipulation.*—Let the case of a liquid be first considered. The piezometer, Fig. 4, clean and dry, is filled with the liquid, which must have been boiled to remove the air in the usual way. This done, a column of mercury several centimetres high is introduced at the lower end of the stem by aid of a funnel, the end of which has been drawn out to as long and fine a point as desirable. This end of the stem is then plunged into a small glass full of mercury, and the body of the piezometer carefully heated until the meniscus reaches the lower end. On cooling the mercury again rises, and the column so formed is very uniform and free from breaks due to the other liquid. Thereafter the stem is provided with a small cylindrical reservoir of steel, and the stem dips into the

## MEMOIRS ON

mercury contained as shown in the figure. It is now necessary to find the mass of the liquid operated on. For this purpose the piezometer is submerged in a long test-tube of glass containing mercury at its lower end, into which the little steel reservoir is plunged. A current of water at constant temperature is made to circulate in the test-tube, and when a state of thermal equilibrium has been reached the volume of the liquid is read off on a standardized scale etched into the lower part of the stem. The piezometer may now be put into the barrel of the pressure apparatus, also charged at its bottom with a sufficient quantity of mercury. The electric circuit is then completed, a spring-stop added to hold the piezometer in place, the attachments for the production of pressure screwed on, and all is now ready for making a series of measurements.

In the case of gases, the following operations are necessary: The current of gas is passed into the piezometer, perfectly dry, and heated from time to time during the operation, and passed out through the fine point at the top. At suitable periods a sample of the gas is tested, and when the examination shows that the piezometer contains perfectly pure gas only, the point at the top is closed with the blow-pipe. Thereafter, without separating the piezometer from the purifying and drying train in which a small excess of pressure is kept in action, the piezometer is received and held vertically by a tube of brass in a special apparatus, which in turn is submerged in a glass trough supplied with a current of circulating water. When the temperature has become stationary, the normal pressure is again established in the dissicating trains, and the rubber tube connecting this apparatus with the lower end of the piezometer, which alone is outside of the bath, is removed with caution. At the same time this end is plunged into a cistern of mercury. This operation to be well made requires some skill and practice. It is now only necessary to fit the small steel thimble to the lower end under mercury, and to place the piezometer in the barrel. All heating which may cause the gas to flow out during the adjustment is to be scrupulously avoided. It is obvious that the pressure of the barometer was taken at the required time, and that the mass of gas is thus perfectly determinate.

All piezometers, whether adapted for liquids or for gases, were calibrated with mercury in such a way that the instant at which

## THE LAWS OF GASES

the mercury touches one of the lateral platinum filaments of the tube is shown electrically precisely in the manner to be adopted during the experiments. The volumes given by the calibration tables are therefore quite identical with the corresponding measurements under pressure.

For the gas piezometers, in particular, this standardization is a rather delicate operation because of the small volumes to be measured. I carried it out in two ways, directly in weight and indirectly in volume. By aid of a standard tube calibrated with great care and temporarily soldered to the stem carrying the platinum contacts, I measured the volume of mercury which is withdrawn from this stem while the column is made to glide from one contact to the next. In this case the small olive-shaped reservoir just below the upper point is calibrated separately. The point, though very fine, is itself calibrated from a fiducial mark onward, in order that the diminution of volume produced when the fine point is cut off and resoldered may be estimated, however small it may be.

### *Plan of a Series of Measurements*

Fig. 5 shows the completed apparatus and its accessories. In the rear of the figure is the tank containing the water to be heated. Constancy of temperature is obtained by the aid of a crown burner of gas, a regulator, an influx tap, and an overflow, all conveniently disposed. For the lower temperatures, water cooled down as far as zero in a refrigerator is raised to any desired degree of temperature by its passage through longer or shorter spirals kept within appropriate temperature baths. On the left is seen the large force-pump communicating with the corresponding stopcock and coupling. Quite in front is the free-piston manometer with the lower end of the mercury column. At the right, on a bracket, is the galvanometer, inserted into the electric circuit to announce the galvanic contacts. It is seen at once how the first instant of contact is obtained. For the others I adopted the following arrangement: The current is branched and the galvanometer mounted differentially. One of the shunts passes through the resistances of the piezometer, a box of resistances, and a rheostat. The galvanometer is put back to zero after each contact, and these are unmistakably indicated by the suppression of a definite quantity of piezometer resistance whenever the contact is

## MEMOIRS ON

made. The force-pump is first to be actuated in order to completely fill the apparatus and to start the excess of internal

FIG. 5.—DISPOSITION OF APPARATUS FOR VERY HIGH PRESSURES

pressure. To find the exact instant of contact use is made of the compressing screw, which, moreover, is employed ex-

## THE LAWS OF GASES

clusively as soon as the pressures reach values of 400 to 500 atmospheres.

When a contact is obtained it is necessary that the apparatus should return again to its initial temperature, since this has been changed by the thermal effect of compression. The initial conditions may be considered as established when, on breaking and reproducing the contact many times by means of small pressure increments slowly applied, it is found to recur uniformly at the same pressure. This pressure is then marked with a fine chalk pencil on the scale of the mercurial column. The galvanometer is now set back to zero, while the compression is continued as far as the next contact, progressing in like manner until the last contact is reached. Thereafter the series is repeated throughout in the opposite direction—*i.e.*, all contacts are passed again in a march of decreasing pressures.

If the series has been carried to completion rather too rapidly, it will happen, owing to the inverse thermal effects during the periods of increasing and decreasing pressures, that the pressures observed in descending will be a little smaller, *caet. par.*, than those observed in ascending. The difference is usually very small, and the mean may be taken. Its value at the same time is a criterion of the degree of accuracy guaranteed.

When the constancy of temperature in the apparatus has been exceptionally good, and if the observer has waited long enough at each contact, the pressures in the ascending series are exactly reproduced by the corresponding pressures in the descending series. This is the best proof which can be given of the trustworthiness of the instrument used in measuring pressures.

Work may be done more expeditiously by completely submerging the piezometer in mercury. The thermal effect of compression is then small, and by reason of the good condition of mercury, the thermal equilibrium is re-established very quickly. In this case, however, the insulation of the resistances requires much greater care.

When the cylinder and the piezometer are filled with water it is perfectly feasible to put in evidence the reversal of the thermal effect of compression on the respective sides of the temperature of maximum density of water.

These operations, which require the concerted observation of

## MEMOIRS ON

at least three persons, are long and tedious. A single series may extend over two, three, four hours, or even more, depending on the number of contacts and supposing that no accident occurs.

I stated above that the prolongation of the unjacketed breech of the steel cylinder seemed to be of excessive length. The reason of this design may be found in an accident which happened to me in the experiments in which oxygen was compressed as far as a maximum density above 1.25 (relative to water) at the temperature of 17° C. The cylinder was quite strong and filled with mercury.\* Suddenly, with a strident noise, a jet of pulverulent mercury was hurled across the right section of the breech, striking the base of the apparatus, rebounding thence to more than a metre in height in all directions. The noise was like that produced by a jet of steam escaping from a boiler under high pressure. A right section of the column after being polished showed nothing in particular when examined under the microscope. We have thus encountered the classical experiment of the rain of mercury through the pores of a body of steel about .08 metre thick. The pressure was certainly as high as 4000 atmospheres. The same apparatus under the same pressure did not admit of the exudation of a single drop of glycerine. It would doubtless have shown the same negative result for water and for other liquids.

No similar accident occurred during the course of my work, so far as a flow normal to the section of the cylinders used is concerned. The reason why the thickness of the breech was increased to an extreme degree in the direction of the axis is, therefore, clear.

I was induced to devise a jacketed cylinder in consequence of an accident of another kind. The first large cylinder of steel which I used (weighing 116 kg.) split apart along opposite generatrices throughout a considerable part of its length. Although there was neither projection nor separation of parts, nor any sudden issue of gas, the rupture was nevertheless accompanied with a detonation of extreme violence. During a few moments the mercury escaped from the fissure, and I had time to observe it in form of a bright metallic plate 6 to 7 cen-

\*. *Comptes Rendus*, March 2, 1885.

## THE LAWS OF GASES

timetres in breadth. It was owing to the occurrence of these two accidents that I added the steel jacket to the cylinder, as already described.

### 3.—APPARATUS FOR HIGHER TEMPERATURES

#### *Method of Sights.*

It would be difficult to work at temperatures markedly higher than those for which the apparatus just described was designed. The mass of the jacketed steel barrel, the presence of the appliances added at its top and which project outside of the bath, would make a uniform degree of high temperature very difficult of attainment. The joints and the cap-shaped washer would no longer insure freedom from leakage. Finally and particularly, for the case of gases, the piezometer stems, fragile at best by reason of the inserted platinum filaments, would become prohibitively so, while the difficulties of an adequate insulation of the parts would in like measure greatly increase.

The following design, which I shall call the method of sights (*méthode des regards*), has enabled me to work as far as  $360^{\circ}$  C. It would even be possible to reach higher temperatures, in modifying the apparatus in the way which experience has suggested, but which I do not expect to apply at present. I have also thought it desirable to restrict the pressures within 1000 atmospheres, although in many trials I went much beyond this.

The method may expediently be described together with the apparatus. The latter is represented in sectional elevation in Fig. 6. In the lower part of the apparatus the jacketed barrel, *HH*, of the preceding compressor will be recognized, although three breaks were needed to shorten the figure. At the top of this is fixed (as above) the apparatus for producing pressure, modified by the introduction of a cross of steel, *A, A, F, F*, forged and thereafter turned and pierced at the lathe throughout the axis of the arms. The horizontal arm, *AA*, carries the bolts, *BB*, screwed to its two extremities, suitably tubulated, in which the sights are cemented with marine glue. These are small cylinders of crown glass or of quartz, with good plane parallel faces, about 1 centimetre in diameter and 2 centimetres long. The joint with the gland is

# MEMOIRS ON

FIG. 6.

FIG. 6.—APPARATUS FOR THE METHOD OF SIGHTS.

FIG. 7.—PIEZOMETER FOR LIQUIDS.

FIG. 8.—PIEZOMETER FOR GASES.

## THE LAWS OF GASES

sealed with a washer of celluloid. The piezometer is mounted symmetrically with the axis of the apparatus, and the figure shows a piezometer of gas in place. Its reservoir is submerged in mercury, which now partially fills the barrel. Its very long stem terminates above in a small olive-shaped reservoir ending in a fine point, as above. Below the enlargement is the graduation, about 25 centimetres long and made of very delicate circular marks narrowing towards the top. Little globular expansions were blown out between them along the lower part of the stem, with the object of virtually increasing the total length of the graduated part. The piezometer is suspended from its upper end by aid of a small pad which is attached to it under the uppermost bulb, and sustained by the aid of a device, *BB*, *CC*, shown enlarged in a separate figure. This piece is connected at *CC* to an intermediate stem of glass joined in the same way at its upper extremity to a long rod of steel. The latter, after having traversed a stuffing-box charged with leather washers, is in its turn joined to the lower end of a long steel screw. This is movable in a socket of brass carried by the same coupling which receives the leather of the stuffing-box. The jacketed barrel, part of the barrel *HH*, is as usual provided with a stopcock (not shown), through which the initial pressures are applied in virtue of the force-pump. Another tube communicates with the manometer. In place of the third coupling, which, in the former case, supplied the electric current, there is now a tube of steel leading to a special steel reservoir, to which the device for producing pressure, formerly described, is suitably attached. High pressure is, therefore, brought to bear at this place by manipulating the lower screw.

The method of experimentation will now be intelligible without much further explanation. By means of the screw at the top of the apparatus, the division-rings on the stem of the piezometer are successively placed in the line of sight. Thereupon pressure is applied until the meniscus appears flush with the division mark, and this pressure is registered. The readings are made with a reading telescope well centred in the line of sight, and the field of vision is illuminated with a simple gas-lamp placed on the opposite side in the same direction. This light is quite sufficient as long as certain precautions are taken which I will now indicate. The injection water rapidly loses its transparency, particularly when the stem is

## MEMOIRS ON

heated. Reading thus becomes more impossible in proportion as the layer of liquid penetrated by the rays is thicker. To obviate this difficulty I at first placed cylinders of crown-glass, plane-parallel and perfectly transparent, throughout the whole length of the channel. Readings at the lower temperatures were then easily made, but at the higher temperatures the faces of the glass cylinder were rapidly attacked in the hot regions and after a time covered over with an opaque pulverulent layer, being thus completely corroded. Hence, in subsequent work I replaced the crown-glass cylinders in the hot parts of the tube by quartz cylinders with their faces normal to the axis. Readings could then be made without difficulty. Again, to avoid the decomposition of leather, which would have clouded the internal faces of the sight-cylinders, the joints in the nuts and valves were sealed with celluloid washers.

The different temperatures at which it was proposed to investigate were obtained by enveloping the arms of the cross, *AF*, by an appliance adapted to do service either as a water-bath or as a vapor-bath. The lower part of this surrounded the three arms permanently, the seal being made with red-lead. The upper part of the bath differed in form according to the uses to be made of it, and it was fitted into a shouldered rim in the lower part and held in place by friction.

To obtain a vapor-bath an appliance with a two-chambered interior was at hand, provided with a perforated bottom. The condenser communicated with the tubulure *F* of the removable lid, which at the same time furnished a support for the thermometers. When a liquid bath was wanted, the partition was replaced by an agitator actuated by a small Gramme machine. Constancy of temperature was then obtained by suitably adjusting the distance and the gas supply of the crown burner seen at the bottom of the bath.

At *D*, under the leather stuffing-box, and at the extremities, *BB*, of the horizontal arms, small water-jackets were added, fed with a current of cold water. This prevented serious overheating of the leather washers or of the mastic seals at the sights. The discharge water flows into the lower reservoir, keeping the joints of the cross, which are plunged in it, cold, and then escapes by a lateral tubulure.

The result of this cooling is that under the stuffing-box, *G*, in particular, the cross reaches the temperature of the bath

## THE LAWS OF GASES

only at a considerable distance below the lid. I thought it worth while to make direct tests by using long, probelike thermometers specially made for this purpose, in order to be properly guided as to the maximum height up to which the tip of the piezometer could be raised at any temperature without encountering seriously reduced values. It would have been far preferable—indeed, at higher temperatures, it would be absolutely necessary to close the cross immediately below the stuffing-box, and to produce the vertical displacement of the piezometer by means of an appropriate appliance attached at the lower end. All this is feasible, though not without difficulty.

### PRELIMINARY OPERATIONS

After what has been said relatively to the first method, only a few words are needed. The piezometers, Figs. 7 and 8, both for liquids and for gases, do not differ from those above described except as to the stems, which now carry the circular division marks in place of the platinum filaments formerly used. They are filled and the mass of the contents determined in identically the same way as before, but it is much more difficult to adjust them in place. This can only be done by a suitable pulley-block fastened to the ceiling, by means of which the cross may be raised or lowered without the least jolting. Even slight percussion would invariably break the stem of the piezometer.

Constancy of temperature is now reached much more rapidly than in the preceding experiments, whether the environment be an ice-bath, a water or a vapor bath; for the total mass which is to reach a stationary temperature distribution is enormously smaller. A full series of experiments is nevertheless tediously prolonged, seeing that the number of division marks on the stem is so much larger than the number of platinum filaments above. As far as  $100^{\circ}$  the temperatures were given by water-baths. A point very near  $200^{\circ}$  corresponds to the boiling-point of methyl benzoate, another at  $260^{\circ}$  to amyl benzoate. Many bodies were tested as to their availability in vapor-baths between  $100^{\circ}$  and  $200^{\circ}$ . For  $140^{\circ}$  I employed xylene and ethyl acetate, but the results were less satisfactory than in the preceding cases. I was quite unable to obtain a perfectly constant temperature from xylene. The specific heat per unit of volume seems to be very small, and the heat

## MEMOIRS ON

transferred insufficient to compensate for the external losses. I shall therefore publish the series made at this temperature with this special reservation.

In all the series of measurements made up to  $100^{\circ}$  by this method, I restricted the observations to an exact number of degrees, using thermometers for this purpose compared in advance with a standard provided by the *Bureau International des Poids et Mesures*, and calibrated by M. Guillaume. They are reduced to the hydrogen thermometer by means of the table of M. Chappuis. At  $100^{\circ}$  either a water-bath or a steam-bath was available. I have given the results for  $100^{\circ}$  exactly, the interpolation being insignificant and no error resulting from it. Temperatures above  $100^{\circ}$  were determined by means of excellent thermometers of hard glass, constructed by M. Chabaud, who also made the piezometers. A preliminary comparison of these instruments with the hydrogen thermometer showed only very small differences, for which allowance was made throughout. There is no room here to give the data for this calibration, as I had hoped to do; but I took into account the displacement of the zero mark by applying a special test after each series of measurements. The variations of this point were small.

However complicated the apparatus itself may appear, the measurements are made with facility, barring accidents, of course. The length of time consumed alone made them tedious. When a division mark has been brought into the field of the telescope, pressure is applied until the mark is tangent to the mercury meniscus, which here appears as a dark demarcation on a luminous background. The adjustment is easily made on compressing with the screw, and this, as in the preceding work, was used exclusively whenever the pressures exceeded a high value. Unfortunately, at high temperatures the action of the water eventually tarnishes the external surface of the graduated stem, and the meniscus appears blurred. Hence it is always necessary to stop after each series made at the higher temperatures, and take the apparatus apart in order to lightly repolish the stem. The operation is easily accomplished with the aid of a polishing wheel, mounted on a lathe. The present corrosion, however, is not to be compared to similar experiences with crown-glass mentioned above. It is for this reason that hard glass piezometers were selected.

Pressures are measured in the way described above. Ob-

## THE LAWS OF GASES

viously, account must be taken of the temperature of the mercury column, of the height of the mercury in the piezometer above its level in the barrel, and of the position of this level relatively to the manometer.

The measurement of small volumes is one of the difficulties of these researches. Without entering into any detail, I will simply state that allowance was made for the form of the meniscus, and of its position with reference to the division mark during calibration and during the subsequent measurements. Only in the case of gases are the errors here in question to be apprehended. Their volumes diminish with extreme rapidity, even when the reservoirs are made as large as is compatible with the dimensions of the barrel.

### PART II.—DATA FOR GASES

The results summarized by the following tables were obtained in experiments of the kind just described.

After adding all corrections, the pressures were first expressed in atmospheres. To find the corresponding volumes, the piezometer may be supposed to be standardized at  $0^{\circ}$  C., seeing that volume ratios alone are in question. Account must be taken, however, when necessary, of the temperature differences occurring when the different parts of the piezometer (stem and reservoir) were calibrated. The corrections due to thermal expansion and to compression were afterwards applied in their turn. In my former researches I have given all the necessary data.

Having found the mass of the fluid in the manner stated above, and recalling that the calibration is supposed to be correct at zero, all the subsequent volumes are reduced to the value they would have if the given mass were that of unit of volume at  $0^{\circ}$  C. and 1 atmosphere. My tables, without exception, refer to this unit. Thereafter I constructed a series of curves corresponding to my data, in which pressures are the abscissas and the products,  $PV$ , of pressure and volume the ordinates. From these curves I selected a series of correlated values of  $PV$ , corresponding to groups of pressures differing in round numbers by 25, 50, or 100 atmospheres, and from them I deduced the values of  $V$ . For carbon dioxide and ethylene I batched the data in smaller pressure intervals because of the

# MEMOIRS ON

complex form of curve observed in the region of the critical point. Supplementary tables are here given.

The data for the pressure coefficient are taken directly from the curves. It sufficed to draw the lines of equal volume, which, under present circumstances, are straight lines passing through the origin, and then to read off the pressures at which these lines cut the successive isotherms. The curves were drawn either as a whole or by distributing them on sheets of millimetre cross-section paper, stretched on a large drawing-board more than 2 meters broad.

The gases studied are oxygen, hydrogen, nitrogen, air, carbon dioxide, and ethylene. The last were operated on by the method of sights only; the other gases by both methods.

## RESULTS OBTAINED BY THE FIRST METHOD

### (Method of Electric Contacts)

I will begin with the results of the first method. The numbers relating to pressures below 500 atmospheres belong to the series of data obtained by the second method. The series found by the method of contacts does not begin until above 500 or 600 atmospheres. The other results are reproduced here so as to give completed series at zero.

## THE LAWS OF GASES

I shall insert here also certain supplementary results obtained from these curves, which will be found useful in correcting the readings of gas manometers. To these I append the results of experiments made in 1864 at Fourvières with the same end in view:

# THE LAWS OF GASES

## EXAMINATION OF THE RESULTS

### *General Laws*

An inspection of the above results will lead to inferences similar in a general way to those which I adduced in my memoir of 1881. I shall now, moreover, be able to examine a

FIG. 9.

great number of moot points, relative to which no decision could certainly have been made by aid of investigations no more extensive than those heretofore available.

It did not seem necessary to give all the curves for the divers

## MEMOIRS ON

gases, seeing that the principal types were drawn in full in my first research. The group of isotherms for carbon dioxide graphically represented within the limits actually reached suffice for exhibiting the results in their general features. The first diagram (Fig. 9) shows the isotherms for this gas, when the pressures are laid off as abscissas and the products  $PV$  as ordinates. The second diagram (Fig. 10) shows the region in

FIG. 10.

the neighborhood of the critical point with more detail. The part of the isotherms represented by dotted lines has been added merely to round off the figures. They have not been made the subject of measurement in the present paper, excepting the lines for  $32^\circ$  and  $35^\circ$ , which are dotted throughout.

At temperatures lower than the critical point, a part of the isotherms is in the form of straight vertical lines, corresponding to liquefaction. These did not occur in my first group of curves, which began at  $35^\circ$ .

The ordinates of the extremities of each straight part show

## THE LAWS OF GASES

the volume in the liquid state and the corresponding volume of the saturated vapor, and hence, also, the densities of the two states, respectively. The locus of these points is Andrews's curve of liquefaction, and has been traced in the second diagram (Fig. 10). Another dotted curve, recalling, as does the preceding, the form of a parabola between the limits of construction, is the locus of the points of minimum ordinates,  $PV$ . The abscissas of this curve pass through a maximum, as was to be anticipated from the facts which I have already indicated elsewhere—*i.e.*, for gases in a region remote from their critical points, like methane, air, nitrogen, the abscissa of the minimum ordinate shows a retrograde march for continually increasing temperatures, an inversion of what took place in the case of carbon dioxide within the field to which I was then restricted. The following table gives the maximum vapor tension, the pressure corresponding to the minimum ordinates at the different temperatures, as well as the value of  $PV$  at that ordinate for the gases oxygen, carbon dioxide, and ethylene :

## MEMOIRS ON

The temperature  $10^{\circ}\text{C.}$ , corresponding to the maximum vapor pressure 51 atmospheres, appears from the form of the isotherms for ethylene to be extremely near the critical temperature. These results are thus approximately identical with the data obtained by Mr. J. Dewar. The method pursued does not admit of a direct determination of the point in question, and critical data can be deduced from the table only by calculation based on the intrinsic equation of the gas.

Quite recently M. Mitkowski,\* in an interesting paper on the compressibility of air, has prolonged the locus of minimum ordinates as far as  $145^{\circ}\text{C.}$ , and has shown that this gas has a maximum abscissa at about  $-75^{\circ}\text{C.}$  and 124 atmospheres.

The form of the isotherms beyond the region of minimum ordinates is one of the questions which I particularly wished to investigate. These curves, beginning with a distance from the ordinates in question, which is smaller in proportion as the temperature is lower, seemed to me to undergo a transformation into lines sensibly straight. I was aware of the existence of slight curvature; but this was so little marked as to suggest that further prolongation of the family of curves would bring out a fascicle of parallel straight lines more and more clearly. In fact, this hypothesis proved to be specially attractive, inasmuch as the angular coefficient of these fascicles severally gave the limit of volume for an infinite pressure. Hence they lead to a very simple interpretation of the *covolume*, thus found directly and with precision.

Unfortunately, this hypothesis of mine does not seem to be verified—at least, within the limits of temperature and pressure of the present research. The isotherms all present a concavity towards the abscissa, slight, it is true, but nevertheless beyond question. Concavity is expressible as a diminution of the angular coefficient of the tangent, and I have summarized the values of the coefficient  $\frac{P'V' - PV}{P' - P} = \epsilon$  in the following table. This gives  $\epsilon$  between the pressure limits given in the first column at the different temperatures indicated in the first row.

\* Académie des Sciences de Cracovie, 1891.

Clearly the isotherms present slight curvature, as pointed out above. Between the same pressure limits the angular coefficient increases by a small amount with temperature. This increment corresponds to widening of the fascicle, which is distinctly seen for the case of carbon dioxide in the region of lower temperatures. As temperature increases the curves gradually cease to spread apart. In the permanent gases—like hydrogen, nitrogen, and air—the variation with temperature is scarcely perceptible.

A comparison of the decrements of these coefficients between the same pressure limits but at different temperatures shows no variation clearly enough indicated to be specified like the preceding; those groups of observations which extend over a sufficient interval of temperature are restricted to a pressure interval of 1000 atmospheres. Whether under sufficiently high pressures and at high enough temperatures the angular coefficient will reach a limiting value cannot, therefore, be foreseen. In all cases the smallest values of these coefficients are superior limits of the smallest volumes possible. It might be interesting to compare these values with those computed by aid of the intrinsic equations. To take the simplest form of equation, that of Van der Waals, the third part of the critical volume is evidently a limit of this reduction.

## MEMOIRS ON

Carbon dioxide, for instance, has a critical volume of .004224, the third of which, .001408, is markedly less than the smallest angular coefficient, .00149.

### COEFFICIENTS OF EXPANSION AT CONSTANT PRESSURE

$$\left(\frac{1}{v} \frac{dv}{dt}\right)$$

The laws of expansion are particularly involved in the neighborhood of the critical point. For temperatures below the critical point the coefficients can obviously not be computed for pressures intermediate between the tension maxima corresponding to the given limits of temperature; for the change of volume here originates not merely in thermal expansion between these states, but is due also to a change of state. In other words, the coefficients are infinite between these limits, and in the following table crosses are put in the place of the two coefficients which, for the reason given, are without meaning.

For pressures equal to the maximum vapor tensions at one of the limits of the temperature interval, the coefficient refers to the gaseous state for the case of the lower limit, and to the liquid state for the case of the upper limit. Hence, for a given temperature and at the corresponding maximum vapor tension, there are two coefficients, belonging, respectively, to the two states of aggregation. One refers to incipient saturation, the other to an absence of vapor. It would be extremely interesting to compare the values of these two coefficients at different temperatures. Such an inquiry, however, would require special investigations, and on the whole present serious difficulties. Since the variation of the coefficient with temperature is very rapid under these conditions, it would be necessary to greatly restrict the temperature interval on approaching saturation.

Two tables follow relative to carbon dioxide and ethylene respectively, in which the mean coefficients of expansion are given for the pressures inserted in the first vertical column. The temperature intervals for which the coefficients apply are shown in the first horizontal row. To avoid misapprehension, it is to be observed that the coefficients are reduced or referred to unit of volume by successively dividing by the volume corresponding to the lower temperature limit, and not by the initial volume at zero centigrade.

## THE LAWS OF GASES

### VARIATION OF THE COEFFICIENT OF EXPANSION WITH PRESSURE

An inspection of Table 21 shows that at the outset the coefficient of expansion changes with pressure, in the manner already specified by Regnault for pressures of a few atmospheres. It then passes through a maximum, which occurs at a pressure regularly increasing with temperature. The maxima in each vertical column of the tables are put in parentheses. During my first researches on this subject I believed that these maxima occur at the same pressure for which the product  $PV$  is a minimum; but the more extended data of the present memoir show this law to be only approximate.

At the critical temperature the maximum coefficient of expansion evidently coincides with the critical pressure, since the former is then infinite. Under other conditions, depending on the form of the isotherm, this pressure is much smaller than the pressure corresponding to the minimum ordinate. The locus of maximum coefficients of expansion thus starts out from the critical point (in my first memoir the initial isotherm was taken at  $35.1^{\circ}$  C.); and since this is a point of double inflection, the inquiry is pertinent whether the locus in question is not identical with the point of inflection of the isotherms. This is not the case. For increasing temperature, the maximum coefficient is always encountered a little earlier than the minimum ordinate. It is thus comprehended between the locus of the summits of these ordinates and the locus of the points of inflection. Little by little it approaches the former, and ends by intersecting it in the region of its minimum abscissa.

Table 22 for ethylene leads to a series of results of an analogous character throughout.

The following table (23) shows for oxygen, hydrogen, nitrogen, and air that the diminution of the coefficient of expansion continues regularly even as far as 3000 atmospheres. The same fact is exhibited in Table 24 for the same gases throughout higher temperatures.

3000	098	098	110	105

## VARIATION OF THE COEFFICIENT OF EXPANSION WITH TEMPERATURE

The above tables, 21 and 22, show that the coefficient at first increases with temperature, passes a maximum, and thereafter diminishes.

Under constant pressures of successively increasing value the maximum occurs at temperatures which continually increase, while the maximum itself becomes less accentuated and finally vanishes within the limits of the tables. An increase of value alone remains, which, in its turn, gradually becomes less appreciable. At 1000 atmospheres the maximum is certainly still encountered at sufficiently high temperatures. To verify these observations it suffices to treat such gases as are much farther removed from their critical points. It is then manifest that the maximum has been reached or even passed in all cases, as, for instance, Table 24 fully evidences. All the coefficients are here notably smaller between 100° and 200° than between 0° and 100°. Hence the maximum has been passed.

# THE LAWS OF GASES

900	261	198	226	182	218	179	226	182
1000	241	—	218	—	—	—	214	171

In Tables 21 and 22 the maxima relative to temperature were put in square brackets. It is seen that they make up a group which lies very close to the maxima relative to pressure, and which, like the latter, would appear with greater regularity if the limits of the temperature and the pressure intervals were both narrower. The real maxima coincide, as it were, accidentally with the numbers in the tables.

The locus of the maxima relative to temperature starts from the critical point, as did the locus of the maxima relative to pressure. It approaches the locus of minimum ordinates more rapidly than the latter, and intersects it sooner, as it were.

Below the critical temperature the first coefficients of each horizontal row in Table 21 refer to the liquid state, since the pressure exceeds the maximum vapor tension. At pressures lower than the critical pressure the coefficients for the gaseous state, properly so called, at once decrease. As early as 1870 I showed\* that for the cases of carbon dioxide and sulphur dioxide the coefficients decrease regularly from 0° C. to above 300° under atmospheric pressure.

For pressures of a value higher than the critical pressure there is no further occasion to consider the distinction between the two coefficients which I have just explained; for the discontinuity no longer occurs under constant pressure. To obviate all misapprehension I have marked three coefficients with an asterisk (\*), which, although corresponding to temperatures

\* *Comptes Rendus*, July 4, 1870; *Annales de Chimie et de Physique*, 1872.

# MEMOIRS ON

below the critical temperature, belong to the gaseous state (at 50 and 60 atmospheres).

To return to the gaseous state : It was shown above that in case of oxygen, hydrogen, nitrogen, and air the coefficient of expansion has passed beyond its maximum value even at ordinary temperatures. The following table (25\*), containing values of  $\frac{\Delta v}{\Delta t}$  not reduced to the unit of volume, proves that the coefficients are practically independent of temperature, oxygen alone excepted :

TABLE 25\*.—VALUES OF  $\frac{\Delta v}{\Delta t} \times 10^3$

P Atm.	OXYGEN		HYDROGEN		NITROGEN		AIR	
	0° to 99.5°	99.5° to 199.5°	0° to 99.25°	99.25° to 200.2°	0° to 99.5°	99.45° to 199.5°	0° to 99.4°	99.4° to 200°

300	1643	1440	1265	1222	1522	1414	1544	1422
400	1207	1072	947	919	1124	1066	1125	1084
500	937	856	754	741	877	859	887	859
600	756	703	624	615	718	715	720	706
700	634	592	535	526	609	609	615	602
800	541	512	468	460	530	525	533	525
900	470	450	415	409	469	463	469	463
1000	418	—	376	—	—	—	425	413

Thus the coefficients beginning with 0° C. are sensibly constant for a given pressure, the same fact which was brought out by Table 23 as far as the highest pressures. Hence the coefficients computed for the successive intervals vary nearly inversely as the successive initial volumes. This appears to be the law towards which the decreasing march which follows the maximum points converges for conditions of increasing temperature. This limiting state is reached sooner in proportion as the pressure is smaller.

Hence, at all pressures and sufficiently high temperatures, this simple law supervenes : the increment of volume is proportional to increment of temperature reproducing the case of perfect gases. In a general way only is the volume proportional to the absolute temperature increased by a constant ; for this constant diminishes as pressure decreases in such a way that if pressure is small enough, the law of the proportionality of vol-

## THE LAWS OF GASES.

ume and absolute temperature is encountered. This again is the law of sensibly perfect gases.

### COEFFICIENTS OF EXPANSION AT CONSTANT VOLUME,

$$\beta = \frac{1}{p} \frac{dp}{dt}, \text{ AND PRESSURE COEFFICIENTS, } B = \frac{dp}{dt}$$

To avoid all confusion, I will call the values  $\frac{\Delta p}{\Delta t}$  *pressure coefficients*. This reserves for  $\frac{1}{p} \frac{\Delta p}{\Delta t}$  the time-honored, but otherwise very curious designation of *expansion coefficient* at constant volume.

In Table 25, on page 102, computed by aid of the data in Tables 6, 12, 17, 18, these coefficients are given relative to the temperature interval inserted at the heads of the vertical columns, and for the constant volume in the first of these columns. The pressures indicated for carbon dioxide and ethylene under the caption "Initial Pressures" do not all refer to zero, but to the lower limit of temperature of the first mean coefficient on the same horizontal row. The tables contain a gap which corresponds to the region contained within the curve of liquefaction.

It must be borne in mind that reduction to the unit of pressure of the coefficients  $\beta$  has been accomplished by dividing by the pressure corresponding to the lower temperature of each interval—at variance, therefore, to the notation frequently adopted. I have already made a similar remark relative to the reduction of the coefficients of compressibility and of expansion under constant pressure to the unit of volume.

## MEMOIRS ON

### VARIATION OF THE COEFFICIENTS $B$ AND $\beta$ WITH VOLUME

The pressure coefficient  $B$  is seen to increase very rapidly when volume decreases—*i.e.*, when the initial pressure at zero increases. The coefficient  $\beta$  (Table 25) at first increases for increasing volume, and thereafter passes through a maximum which is much less pronounced when the temperature is higher. Finally  $\beta$  decreases with increasing volume. In case of nitrogen the maximum is not yet reached between  $0^\circ$  and  $200^\circ$  within the pressure limits given in Table 26. For hydrogen, on the contrary, its occurrence falls within the same limits, since  $\beta$  is then sensibly constant. For the highest pressures the maximum has been passed by in case of each of the four gases in Table 27.

### VARIATION OF THE COEFFICIENTS $B$ AND $\beta$ WITH TEMPERATURE

Generally speaking, the coefficient  $B$  varies very little with temperature. An inspection of the table shows for carbon dioxide between  $0^\circ$  and  $100^\circ$  that this variation is quite insignificant. This is the identical result reached in my research\* of 1881. Some time after Messrs. W. Ramsay and Sidney Young published important researches on the same subject, to which I shall recur on another occasion.

Between  $100^\circ$  and  $260^\circ$ ,  $B$  shows a slight diminution. This is also true for the case of ethylene.

For hydrogen, air, and nitrogen the variation of  $B$  between  $0^\circ$  and  $200^\circ$  (Table 26) is scarcely apparent, particularly after the pressures approach the high values. A similar influence may be drawn for the other three gases (Table 27) for a pressure interval quite up to the highest pressures. It must be observed, however, that these results are restricted to smaller temperature intervals.

It appears to follow from the results as a whole that the variation of the pressure coefficient with temperature, *always very small*, quite vanishes at sufficiently high temperatures and probably at all temperatures under sufficiently high pressures. This is evidenced by the results shown by those gases which, within the temperature limits of the present research, are al-

\* *Annales de Chimie et de Physique*, 5<sup>e</sup> Série, vol. xxii.

## THE LAWS OF GASES

ready in a thermal state far above their critical points. Under these conditions the pressures corresponding to constancy of volume are not proportional to the respective absolute temperatures; they are proportional to them when each is diminished by a constant function of volume only. This constant is numerically a number of degrees, and it at first increases rapidly when volume diminishes; thereafter it passes through a maximum, decreases passing through zero into negative values, and continues to decrease in absolute value. Whenever this constant vanishes the gas is clearly characterized by the law of perfect gases, and this happens in the case of hydrogen at about 800 atmospheres. It is exceedingly remarkable that under these special conditions the value of the pressure coefficient is nearly equal to the value which holds for normal pressure—*i.e.*, to that attributed to gases when they approach as nearly as possible to the state of a perfect gas. It would be extremely interesting to discover whether the observation in question is of general significance. Unfortunately, the other gases studied have not under the highest pressures applied reached the state for which the constant in question vanishes.

The variations of the constant  $\beta$  may be deduced from what has just been stated. In every case this coefficient for a given volume varies very nearly inversely to pressure. In the region comprised within the curve of liquefaction, and corresponding to the gap in Table 25 (carbon dioxide), there is no true pressure

coefficient. The values  $\frac{dp}{dt}$  now refer to the maximum vapor tensions and no longer vary with volume. Necessarily an abrupt variation of these values occurs on breaking across the curve of liquefaction, excepting, perhaps, the line of equal volumes, which passes through the critical point with an inversion of the sign of the variation on one side or the other of this line. Indeed, it is easily observed that the values of  $\frac{dp}{dt}$  for the lines of equal volume passing above the critical point and near the curve of saturation are smaller on the outside than on the inside of this curve. The contrary will be the case for the lines of equal volume which pass below the critical point. In every case the above inferences relative to pressure coefficients seem to be immediately applicable as soon as the curve of liquefaction is left behind.

# MEMOIRS ON

The isotherms below the critical point are difficult to map out in those parts which are contiguous with the curve of liquefaction. This curve cannot be obtained by means of the above experiments as accurately as may be done by comparing the densities of the liquid and of the vapor obtained in experiments specially designed for this purpose. I have carried out measurements of this kind for carbon dioxide between zero and the critical point; but I will not enter into details relative to these results,\* as they lie outside of the scope of the present investigation, beyond giving a tabulated view of the data. The agreement between the present values of maximum vapor tension and those contained in the above tables is apparent. The same research furnished the following elements of the critical point:

Critical temperature..... 31.35°  
 Critical pressure..... 72.9 atm.  
 Critical density..... 0.464

## THE LAWS OF GASES

I have not up to the present time been able to repeat the same work for ethylene.

Certain other properties of the isotherms for carbon dioxide and ethylene, as well as divers inquiries of a more theoretical kind, are not in place here. In the present memoir, as well as in the following work relating to liquids, I have purposed merely to exhibit the experimental methods, to publish the numerical results obtained, and to deduce from them such general laws as result from inspection.

ÉMILE HILAIRE AMAGAT was born on the 2d of January, 1841, at *St. Satur*, a village in the *arrondissement de Sancerre*, in the *Département du Cher*. It was at first his intention to be a technical chemist, but he abandoned this career almost at the very outset in preference of one in pure science.

For several years Amagat was *préparateur* of the celebrated Berthelot at the *Collège de France*. After this (between 1867 and 1872) he was called to Switzerland, where he served as professor at the *Lycée de Fribourg*. It was there that Amagat completed his *thèse de doctorat*, being formally honored with this degree in Paris in 1872.

Returning to France, he was successively made professor at the *Lycée d'Alençon*, à l'*École Normale Spéciale de Cluny*, and in 1877 was appointed professor of physics in the *Faculté Libre des Sciences* of Lyons. In this institution, then merging into active existence, he created the department of physics, and in it conducted his most famous researches.

He left Lyons in 1891 for Paris, where he resides at present in the official position of *examineur à l'École Polytechnique*.

Amagat has been correspondent of the *Institut de France* (Académie des Sciences, Section de Physique) since 1889. He was elected a foreign member of the *Royal Society of London* in 1897, and of the *Royal Society of Edinburgh* in the same year. He is honorary member of the *Société Hollandaise des Sciences*, of the *Société Scientifique de Bruxelles*, of the *Philosophical Society of Manchester*, etc., etc.

## BIBLIOGRAPHY

AMONG Amagat's papers those bearing particularly on the laws of gases may be summarized for the reader's convenience as follows. A complete list of Amagat's researches will be found in a pamphlet published by Gautier-Villars et fils, Paris, 1896, entitled : *Notice sur les Travaux Scientifiques de M. E. H. Amagat*.

### CRITICAL STATE

- Andrews, *Philosophical Transactions*, **166**, 421-449, 1876.
- Caillietet and Colardeau, *Annales de Chimie et de Physique* (6), **25**, 519, 1892.
- Mathias, E., *Journal de Physique* (3), **1**, 53, 1892.
- Kuenen, J. P., *Philosophical Magazine*, **44**, 1897.

THE END.

# TEXT-BOOKS IN PHYSICS

---

## THEORY OF PHYSICS

By JOSEPH S. AMES, Ph.D., Associate Professor of Physics in Johns Hopkins University. Crown 8vo, Cloth, \$1 60; by mail, \$1 75.

In writing this book it has been the author's aim to give a concise statement of the experimental facts on which the science of physics is based, and to present with these statements the accepted theories which correlate or "explain" them. The book is designed for those students who have had no previous training in physics, or at least only an elementary course, and is adapted to junior classes in colleges or technical schools. The entire subject, as presented in the work, may be easily studied in a course lasting for the academic year of nine months.

Perhaps the best general introduction to physics ever printed in the English language. . . . A model of comprehensiveness, directness, arrangement, and clearness of expression. . . . The treatment of each subject is wonderfully up to date for a text-book, and does credit to the system which keeps Johns Hopkins abreast of the times. Merely as an example of lucid expression and of systematization the book is worthy of careful reading.—*N. Y. Press.*

Seems to me to be thoroughly scientific in its treatment and to give the student what is conspicuously absent in certain well-known text-books on the subject—an excellent perspective of the very extensive phenomena of physics.—PROFESSOR F. E. BEACH, *Sheffield Scientific School of Yale University.*

## A MANUAL OF EXPERIMENTS IN PHYSICS

Laboratory Instruction for College Classes. By JOSEPH S. AMES, Ph.D., Associate Professor of Physics in Johns Hopkins University, author of "Theory of Physics," and WILLIAM J. A. BLISS, Associate in Physics in Johns Hopkins University. 8vo, Cloth, \$1 80; by mail, \$1 95.

I have examined the book, and am greatly pleased with it. It is clear and well arranged, and has the best and newest methods. I can cheerfully recommend it as a most excellent work of its kind.—H. W. HARDING, *Professor Emeritus of Physics, Lehigh University.*

I think the work will materially aid laboratory instructors, lead to more scientific training of the students, and assist markedly in incentives to more advanced and original research.—LUCIEN I. BLAKE, *Professor of Physics, University of Kansas.*

It is written with that clearness and precision which are characteristic of its authors. I am confident that the book will be of great service to teachers and students in the physical laboratory.—HARRY C. JONES, Ph.D., *Instructor in Physical Chemistry, Johns Hopkins University.*

# STANDARDS IN NATURAL SCIENCE

---

## COMPARATIVE ZOOLOGY

Structural and Systematic. For use in Schools and Colleges. By JAMES ORTON, Ph.D. New edition, revised by CHARLES WRIGHT DODGE, M.S., Professor of Biology in the University of Rochester. With 350 illustrations. Crown 8vo, Cloth, \$1 80; by mail, \$1 96.

The distinctive character of this work consists in the treatment of the whole Animal Kingdom as a unit; in the comparative study of the development and variations of organs and their functions, from the simplest to the most complex state; in withholding Systematic Zoology until the student has mastered those structural affinities upon which true classification is founded; and in being fitted for High Schools and Mixed Schools by its language and illustrations, yet going far enough to constitute a complete grammar of the science for the undergraduate course of any college.

## INTRODUCTION TO ELEMENTARY PRACTICAL BIOLOGY

A Laboratory Guide for High Schools and College Students. By CHARLES WRIGHT DODGE, M.S., Professor of Biology, University of Rochester. Crown 8vo, Cloth, \$1 80; by mail, \$1 95.

Professor Dodge's manual consists essentially of questions on the structure and the physiology of a series of common animals and plants typical of their kind—questions which can be answered only by actual examination of the specimen or by experiment. Directions are given for the collection of specimens, for their preservation, and for preparing them for examination; also for performing simple physiological experiments. Particular species are not required, as the questions usually apply well to several related forms.

## THE STUDENTS' LYELL

A Manual of Elementary Geology. Edited by JOHN W. JUDD, C.B., LL.D., F.R.S., Professor of Geology, and Dean of the Royal College of Science, London. With a Geological Map, and 736 Illustrations in the Text. New, revised edition. Crown 8vo, Cloth, \$2 25; by mail, \$2 39.

The progress of geological science during the last quarter of a century has rendered necessary very considerable additions and corrections, and the rewriting of large portions of the book, but I have everywhere striven to preserve the author's plan and to follow the methods which characterize the original work.—*Extract from the Preface of the Revised Edition.*
